a Analyses the feasibility structure of 100 feasible solutions and b that of unfeasible solutions to equations (2) and (3), with scaled interaction strength  $\gamma = 0.8$  ( $g = 0.16$ ). A zero entry means that no feasible subsystem was found among the 2,000 tested.

unfeasible solutions ('non-survivors'), processed in exactly the same way. Even for  $m = 16$ , where the percentage feasible is least (6%), of the 2,000 subsystems examined, 122 were feasible, compared with the control group figure of zero.

To consider what these results mean, we should relate them to existing concepts of complex-system structure. Here, looking at the quantitative features of a definite model, we can confirm and significantly develop some of these mainly qualitative ideas. The concept is familiar, for example, of a persistent system built up from subsystem components which are themselves persistent. Thus the above results may be viewed as a concrete realization of, for example, Simon's 'Chinese box' picture<sup>8</sup>; but in further and important respects, it differs strikingly from all the previous realizations known to us.

The 'nesting' of subsystems is usually seen as achieved by linking them 'externally' to each other, so that  $k$  subsystems, each of order  $m$ , form a system of order  $km$ . Such an arrangement relates well to the needs of control theory, where an externally imposed negative feedback can stabilize each subsystem, and the links between subsystems can be made deliberately weak to preserve overall stability (see for example ref. 9, Ch. 1, 2). This concept seems particularly well adapted to subsystems which are 'mechanical', both in the everyday sense as well as Bertalanffy's more general one<sup>10</sup>.

However, the subsystems in the model above cannot be seen as just 'externally' linked in this way. On the contrary, the feasible subsystems of a given order overlap each other to an extraordinary degree. If we look once again at the least feasible case ( $m = 16$ ), we easily calculate that each 25-species system contains, on average, over 120,000 feasible subsystems of order 16; a pair of these subsystems have, on average, over 10 species in common. Another striking comparison is provided by the feasible 5-species subsystems: the most economical Chinese box packing would need just five of these—the average above is over 15,000.

This overlapping suggests what might be termed a 'third level' on which to characterize a complex system. On the first level, we specify the single-species properties (intrinsic increase rate, and self-regulation parameter ( $s$ )) and on the second level, the pair interactions. The third level concerns the details of 'persistence structure', that is, the nesting and degree of overlap of component subsystems which are themselves viable. Such a characterization would be possible, and perhaps of some use, even when first- and second-level knowledge was deficient or altogether absent (as in catastrophe theory).

A further novelty in this model should be stressed—the strength of interaction involved. When the links between subsystems are external, stability is easiest to assure by keeping the interaction strength down to values within the 'weakly interacting' region. In our case, this corresponds to  $\gamma < [M - 1]^{-1} = 0.04$ . (The system is then biased towards stability by the Gersgorin criterion<sup>11</sup>.)

The value used above is 20 times greater ( $\gamma = 0.8$ ), therefore we are well into the 'significant' region. It is only here (Ashby's 'richly joined' case<sup>12</sup>) that system properties are primarily determined by the interactions; in the weaker regime, the behaviour of the isolated components is only weakly modified by the interactions.

These considerations suggest, then, that the nested, overlapping structure found in the model may be generally required if a truly autonomous ('natural') system is to persist in time, when

the interactions are numerous and strong enough to produce fully developed system behaviour. The robustness of such a structure, and the formidable difficulties in trying to reproduce it artificially (whether *ab initio* or after damage) when no control level is present, are apparent.

## Why are fetal muscles slow?

A. M. Kelly & N. A. Rubinstein

Departments of Pathobiology, School of Veterinary Medicine and of Anatomy, School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania 19174

**Differentiating fast and slow mammalian muscles contract slowly at birth and increase their speed during the first few weeks of life<sup>1,2</sup>. However, only small proportions of slow myosin light chains are found in early developing muscles and the fast type of light chains predominate<sup>3–7</sup>. In addition, differentiating muscle contains unique, embryonic forms of myosin which may partially determine the early slow responses<sup>8–15</sup>. The present study suggests additional reasons for these slow twitch times. Most skeletal muscles are initially formed from a small population of primary generation cells<sup>16,17</sup> which are innervated by pioneering axons early in myogenesis<sup>18</sup>. Subsequently, numerous secondary generation cells develop along the walls of primary myotubes, then separate and become independent units of contraction. Using affinity-purified antibodies to fast and slow myosin<sup>5</sup>, it was found that most primary myotubes react with anti-slow myosin and are destined to become slow, Type I fibres. By contrast, secondary generation cells stain exclusively with anti-fast myosin and develop into Type II, fast fibres. We propose that primary myotubes constitute the fundamental motor units of the developing neuromuscular system and are responsible for early slow movements. Secondary generation cells become organized into large, fast motor units later in development, eclipsing the original slow response.**

Serial, frozen sections were prepared from the extensor digitorum longus (EDL) and soleus muscle of fetal, neonatal and adult rats. At 16 days gestation primordia of the EDL and soleus stain with anti-fast myosin and the reaction with anti-slow is equivocal. Specification into fibre types in the EDL occurs between 17 and 18 days<sup>19,20</sup>. This muscle is then composed of

**Fig. 1** Serial sections of the EDL from an 18-day fetus stained by the indirect peroxidase anti-peroxidase method<sup>20</sup> with anti-fast myosin (*a*) and anti-slow myosin (*b*). The muscle primordium is mainly composed of large primary myotubes most of which stain with both anti-fast and anti-slow myosin. There are a few secondary generation cells attached to the walls of primary myotubes. All of these react strongly with anti-fast and weakly, if at all, with anti-slow myosin (arrows). The large myotubes containing anti-slow myosin are least numerous on the lateral side of the muscle (L). They are interpreted as components of fundamental motor units in the evolving neuromuscular system.  $\times 210$ .

150 to 200 large, primary myotubes most of which stain intensely with both anti-fast and anti-slow myosin (Fig. 1). There are numerous, less differentiated, secondary generation cells clustered around the walls of the primary myotubes, which stain intensely with anti-fast and weakly, if at all, with anti-slow myosin.

At 2 days post partum, comparable numbers of large fibres in the EDL stain with both anti-myosins (Fig. 2), but they are now widely separated by intervening fibres which stain only with anti-fast myosin. We interpret fibres staining with both anti-myosins as the primary generation cells, within which reactivity to anti-slow myosin is intense whereas the response with anti-fast is weak. This suggests that slow myosin is starting to dominate these cells and they are differentiating into Type I fibres (Fig. 2*b, c*). Studies of the adult EDL stained with anti-myosins and myofibrillar ATPase support this—there are approximately 200 Type I fibres amongst a total population of about 4,000 (ref. 21). Other fibres, which number at least 2,000 by 2 days, stain with anti-fast and not with anti-slow myosin. These correspond to the secondary generation cells which have now separated from primary cells and become independent

units of contraction. We interpret them as the precursors of Type II fibres. This pattern of assembly results in primary and secondary generation cells which are intermingled in a mosaic reminiscent of the checkerboard distribution of histochemically distinct fibres in adult muscle<sup>22,23</sup>.

**Fig. 2** Serial sections of the EDL at 2 days post partum stained by direct fluorescence with anti-fast myosin (*a, c*) and anti-slow myosin (*b, d*). Almost all fibres stain intensely with anti-fast myosin. There are a few, widely distributed fibres which stain weakly with anti-fast myosin (arrows, *c*). This selected population stains intensely with anti-slow myosin (arrows, *d*). These fibres are least numerous on the lateral side of the muscle (L) and correspond in distribution to the primary myotubes of the fetal EDL. They are interpreted as developing Type I fibres. Fibres staining only with anti-fast myosin are interpreted as secondary generation differentiating into Type II fibres. *a, b*  $\times 75$ ; *c, d*  $\times 140$ .

**Fig. 3** Serial sections of the 18-day fetal soleus stained by the indirect peroxidase, anti-peroxidase method with anti-fast myosin (a) and anti-slow myosin (b). All fibres stain with both antibodies. There are very few secondary generation cells. At 2 days post partum (c, d, direct fluorescence) the intensity of staining with anti-fast myosin of large primary fibres has decreased but is intense with anti-slow myosin (d). In addition, there are now secondary generation cells developing along the walls of primary fibres all of which stain with anti-fast and not with anti-slow myosin. a, b  $\times 170$ , c, d  $\times 190$ .

Previous studies imply a close dependence of slow myosin synthesis on stimulation by the nervous system<sup>6,24,25</sup>. In the 18-day EDL, primary myotubes are innervated and contain differentiating endplates<sup>20</sup>. The appearance of slow myosin within these cells thus correlates with the development of neuromuscular relations. In addition, reflex hind limb movements develop in the fetus at approximately the same stage of gestation<sup>26-28</sup>, implying that motor unit activity is evolving. Hence we interpret the development of slow myosin within most primary myotubes as the reflection of a fundamental neuromuscular organization. In view of the muscle architecture, movements of the EDL at 18 days must be predominantly generated by primary myotubes containing significant proportions of slow myosin, which may be one reason why early contractions of the EDL are slow.

Secondary generation cells seem not to be separately innervated when in contact with primary myotubes<sup>6,29,30</sup>. Many do not extend the entire length of the muscle<sup>16,31</sup> but are attached to the primary cells by various forms of membrane junction. It is therefore doubtful that they can contract and relax independently. As the muscle matures, they gain independence<sup>16,31</sup> and a separate nerve supply<sup>32</sup>. We propose that they are then added as developing fast motor units to the contractile machinery and as this occurs, they prevail over the early slow response and the muscle increases its speed of contraction.

Differentiation of the soleus follows the same pattern but the temporal sequence and ratio of primary to secondary fibres is different. Using our antibodies the 18-day fetal soleus is the only primordium amongst leg muscles in which almost all fibres stain uniformly with both anti-fast and anti-slow myosins (Fig. 3). In this muscle the results are consistent with those of Gauthier *et al.*<sup>33</sup>. One reason for the uniformity of staining is that this primitive soleus is composed of myotubes which are small and have little variation in size. We interpret these as the primary myotubes of the soleus and there is little evidence of secondary orders of cells as in the EDL at this stage. Thus the soleus seems less developed than the EDL at 18 days.

Development of secondary generation fibres is evident in the soleus at 2 days post partum where their strong reactivity with anti-fast myosin contrasts with the less intense response of the larger primary generation fibres (Fig. 3c, d). As in the EDL, these secondary generation cells do not stain with anti-slow myosin whereas staining of primary fibres is intense. Slow myosin thus is the dominant species in the primary generation cells, which seem to be progressing towards Type I differentiation. Secondary generation cells are progressing towards Type II differentiation. They are as numerous as primary cells in the soleus at 2 days. Significantly, using myofibrillar ATPase stains, there are equal numbers of Types I and II fibres at 15 days post partum<sup>6</sup>.

These findings suggest that initial movements of the soleus, as in the EDL, result from contraction of primary fibres. They contain abundant slow myosin and slow rates of contraction may be anticipated. After birth, secondary generation, fast fibres appear and, once independent, these cells become separately innervated and are added as fast motor units to the original slow response. This may explain why the twitch time course of the soleus is initially slow and then becomes faster in the first few weeks of life. The work of Kugelberg<sup>34</sup> showing the transitions of whole motor units from fast to slow in the maturing animal accounts for the final slowing of the muscle.

This study was supported by NIH grants HL 15835 to the Pennsylvania Muscle Institute, NS 14332, BRSG 5 207, RR5464 and by a grant from the Muscular Dystrophy Association of America. We thank Dr Gerta Vrbova for first suggesting the interpretation of our fluorescence micrographs in terms of developing motor units.

## Anti-inflammatory steroids reduce tissue PG synthetase activity and enhance PG breakdown

P. K. Moore\* & J. R. S. Hoult

Department of Pharmacology, King's College, Strand, London WC2R 2LS, UK

Anti-inflammatory steroids reduce prostaglandin (PG) synthesis in intact cells and isolated organs<sup>1–9</sup> by interfering indirectly with the phospholipase(s) which release the polyunsaturated fatty acid precursors for both cyclooxygenase and lipoxygenase pathways. This action requires nucleic acid transcription and synthesis of new protein,<sup>10–12</sup> and a soluble factor capable of inhibiting PG generation has been identified<sup>11,13</sup>. However, it is not known whether these steroids affect either the actions or content of the enzymes of the PG system after administration *in vivo*, nor is it known if they affect PG-metabolizing enzymes. We show here that treatment of rats with anti-inflammatory steroids causes rapid changes in tissue activities of enzymes which synthesize and inactivate PGs, with apparent levels reduced and increased respectively.

Tissue activities of enzymes which synthesize and break down PGs were assayed by preparing homogenates of organs taken from animals pretreated with anti-inflammatory steroids or with vehicle alone. PG synthetase activity was generally measured by assaying the conversion of arachidonic acid to bioassayable PG-like material in freshly prepared 100,000g microsomal preparations<sup>14,15</sup>, whereas that of the PG-metabolizing enzymes (here called 'prostaglandinases') was assayed by a radiochemical method using the 100,000g cytosolic supernatants and radiolabelled PGF<sub>2α</sub> as substrate<sup>14,15</sup>.

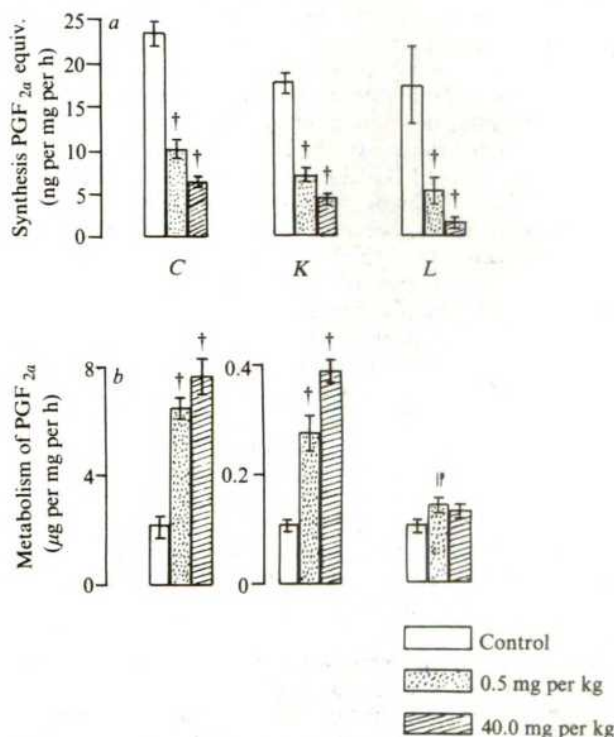

Treatment of rats with prednisolone, 0.5 and 40.0 mg per kg, for 10 days produced a dose-related decrease in activity of microsomal PG synthetase in caecum, kidney and lung; by contrast, the activities of prostaglandinase in these organs were increased (Fig. 1). An experiment investigating the time course of these reciprocal changes in the PG system showed that they occurred within 48 h, that is, after two subcutaneous injections of prednisolone, in caecum and kidney (Table 1) as well as in stomach (not shown).

Further experiments using prednisolone at 0.5, 5.0 and 40.0 mg per kg (given for 2 days only) also elicited dose-related decreases in apparent PG synthetase levels and increased prostaglandinase activity in stomach, caecum and kidney. The lowest

dose is similar to that recommended for a variety of clinical applications in man (10–100 mg per day)<sup>16</sup>. Several other anti-inflammatory steroids were tested at doses selected to reflect their established clinical potencies. As expected, these treatments caused a reduction in apparent microsomal PG synthetase activity, and in most cases also increased the prostaglandinase activity (Table 1). Correlations between anti-inflammatory potency and the anti-phospholipase actions of these steroids have been noted previously<sup>6,9</sup>.

Taken together, the results suggest that these pharmacological effects of the glucocorticoids on the enzymes of the PG system might be related to their anti-inflammatory properties. To test this idea we treated rats with cortisone, 17 $\alpha$ -methyltestosterone and tetrahydrocortisone (all at 20 mg per kg for 2 days), but they did not produce typical steroid-like reciprocal changes (Table 1). These therapeutically inactive compounds are closely related to hydrocortisone and may bind to glucocorticoid receptors, but are not agonists<sup>17</sup>. In most cases the treatments caused small changes in enzyme activities in the opposite direction (and represented in Table 1 as negative values), although in most cases the changes were not significant.

The simplest explanation for our findings is that the anti-inflammatory steroids modify cellular protein synthesis such that the amounts or levels of PG synthetase are decreased and those of PG-metabolizing enzymes increased. However,

**Fig. 1** Treatment of rats with prednisolone at 0.5 and 40.0 mg per kg for 10 days decreases activity (apparent level) in caecum (C), kidney (K) and lung (L) of microsomal PG synthetase (a), and increases activity of prostaglandin-metabolizing enzymes (b). Male Sprague-Dawley rats (five or six per group, 200 g) were injected with prednisolone sodium succinate or 0.2 ml vehicle (0.9% saline containing 0.5% CM-cellulose, 0.4% Tween 80 and 0.9% ethyl alcohol). Low-dose prednisolone animals appeared normal, but the growth and spleen size of rats treated with prednisolone 40 mg per kg were much reduced. However, histological examination of sections of stomach, lung and kidney did not reveal any differences between tissues from the three treatment groups. Organs were worked up individually as previously described<sup>14,15</sup> and assayed for PG metabolism (100,000 g supernatants incubated at 37 °C pH 7.5, with 5 mM NAD<sup>+</sup>, 0.05 μCi [<sup>3</sup>H]-PGF<sub>2α</sub> and 10 μg ml<sup>-1</sup> PGF<sub>2α</sub> and extracted for radio-TLC caecum 5 min, kidney 60 min and lung 90 min incubation), or PG synthesis (100,000g microsomes pooled and resuspended for 60 min incubation at 37 °C pH 7.5, with 10 μg ml<sup>-1</sup> arachidonic acid, 3 mM reduced glutathione and extracted for bioassay using PGF<sub>2α</sub> as reference standard). Results show means  $\pm$  s.e.m. for 6–12 determinations and are expressed in terms of protein content (not different between experimental groups for any single organ) using bovine serum albumin as standard. The significance of differences was evaluated using Student's *t*-test, and the key symbols are the same as those used in Table 1.

\* Present address: Department of Pharmacology, Chelsea College, Manresa Road, London SW3 3TW, UK.

Groups of three or four rats were injected daily for 2–8 days with steroids as indicated. Doses refer to base: the steroids (all Sigma) were in the form corticosterone 21-acetate, triamcinolone acetate, dexamethasone acetate, prednisolone sodium succinate, hydrocortisone 21-acetate, fludrocortisone acetate, tetrahydrocortisone, cortexolone (=11-deoxycortisol) and 17 $\alpha$ -methyltestosterone. Enzyme activities are expressed as per cent change relative to vehicle-injected control rats. Results show mean  $\pm$  s.e.m. for 4–10 determinations. Each block of results represents experiments with different batches of Sprague–Dawley rats.

\* Relative anti-inflammatory potency, hydrocortisone = 1 (from ref. 16).

†  $P < 0.001$ ; ‡  $P < 0.002$ ; §  $P < 0.01$ ; ||  $P < 0.02$ ; ¶  $P < 0.05$ ; # not significant relative to control treated rats, using Student's *t*-test.

alternative explanations are possible, and for this reason we refer to the changes in terms of 'activities' rather than 'levels'. It is recognized that many of the varied metabolic effects of glucocorticoids (and other steroid hormones) occur as a result of changes in the rates of synthesis of specific proteins<sup>18,19</sup>.

It is unlikely that the PG synthetase results can be accounted for by a redirection of PG endoperoxide breakdown away from PGE<sub>2</sub> and PGF<sub>2 $\alpha$</sub>  formation towards other non-spasmogenic prostanoid derivatives, because the reaction conditions (high substrate concentration, presence of reduced glutathione) favour the formation of the classical PGs (refs 20, 21). Furthermore, we obtained direct evidence from radiochemical experiments that the conversion of arachidonic acid to the various prostanoid products was reduced in freshly prepared homogenates of kidney, spleen and stomach prepared from rats treated for 2 days with prednisolone at 40 mg per kg. The overall percentage utilization of 0.5  $\mu$ g ml<sup>-1</sup> arachidonic acid (labelled with 0.4  $\mu$ Ci [1-<sup>14</sup>C]-arachidonic acid, Radiochemical Centre, specific activity 56.4 Ci mol<sup>-1</sup>, no cofactor added) in 10-min incubations decreased from 41.0  $\pm$  5.9 to 20.0  $\pm$  4.9 in kidney, from 56.9  $\pm$  5.3 to 10.9  $\pm$  0.4 in spleen and from 26.7  $\pm$  1.5 to 7.1  $\pm$  2.6 in stomach, results obtained using six control and three steroid-treated animals.

We have shown that the activity of PG-metabolizing enzymes is increased in steroid-treated rats and believe that this may reflect increased tissue levels of prostaglandin 15-hydroxy-dehydrogenase (PGDH, the first enzyme in the PG degradative pathway<sup>22</sup>). However, we cannot exclude the possibility that these changes can be partly explained by the presence in the supernatants of factor(s) which enhance PGDH activity (see accompanying paper<sup>23</sup>) rather than by increases in PGDH levels. Nevertheless, this factor cannot be the steroid itself: in the range 1  $\mu$ M to 1 mM, prednisolone (four tests each at four concentrations) did not affect PGF<sub>2 $\alpha$</sub>  breakdown in 60-min incubations of rat kidney 100,000g supernatant.

To confirm these findings, prostaglandinase activities in supernatants were also measured by bioassay of the rate of disappearance of 10  $\mu$ g ml<sup>-1</sup> PGE<sub>2</sub> and PGF<sub>2 $\alpha$</sub>  from incubations of kidney and caecum. PGE<sub>2</sub> metabolism was more rapid than that of PGF<sub>2 $\alpha$</sub> , consistent with the known affinities of these PGs for PGDH<sup>22</sup>. A plot of disappearance of PGF<sub>2 $\alpha$</sub>  activity against time in 100,000g supernatants of kidney prepared from rats pretreated for 2 days with prednisolone 40 mg per kg showed it to be accelerated (*t*<sub>1/2</sub> ~ 10 min compared with ~ 32 min in control kidney). Both PGE<sub>2</sub> and PGF<sub>2 $\alpha$</sub>  inactivation in caecum and kidney were enhanced in the steroid-treated rats.

Our results show that in the rat, pharmacological doses of anti-inflammatory steroids administered *in vivo* have a more pervasive 'anti-prostaglandin' effect than has previously been realised: they cause bidirectional enzymatic changes which may lead to reduced tissue PG synthesis and enhanced breakdown. We believe that the effects relate directly to their anti-inflammatory actions because PGs and related substances have predominantly pro-inflammatory properties<sup>24,25</sup>; however, this effect is likely to be only one among many which contribute to the powerful anti-inflammatory spectrum of these compounds (see refs 16, 26). Although we do not understand how the changes in enzyme activities are brought about, it is probable that they reflect altered tissue levels of the enzymes concerned; this in turn suggests dependence on changes in cellular protein synthesis in the manner described for the steroid-induced release of anti-phospholipase factor<sup>11,13</sup>.

We thank Dr J. E. Pike (Upjohn) for gifts of prostaglandins, the MRC and May & Baker Ltd for financial support and Dr J. G. Hoult and P. D. Brinck for assistance with histological studies.

## Pathophysiological states modify levels in rat plasma of factors which inhibit synthesis and enhance breakdown of PG

P. K. Moore\* & J. R. S. Hoult

Department of Pharmacology, King's College, Strand, London WC2R 2LS, UK

We have shown recently that adaptive changes in the apparent amount of enzymes which synthesize and inactivate prostaglandins (PGs) occur in a reciprocal manner (see accompanying paper<sup>1</sup> and refs 2–4). For example, PG synthetase activity in several rat organs is reduced but that of PG-metabolizing enzymes ('prostaglandinases') is increased after treatment with anti-inflammatory steroids<sup>1</sup>. In view of recent reports that the synthesis of PG-like substances may be influenced by plasma factors<sup>5–7</sup>, we wondered whether our findings may be explained in whole or in part by the presence in varying amounts of substances which affect PG synthesis and inactivation in opposite directions. We show here that rat plasma contains a protein factor(s) which inhibits the synthesis of PGs and enhances their enzymatic breakdown *in vitro* and which we provisionally call prostaglandin 'reciprocal coupling factor' (RCF). Furthermore, RCF is rapidly released in response to anti-inflammatory steroids and its levels are altered in the two model pathophysiological states so far investigated.

The effects of plasma from male rats were tested in standardized assays of PG synthesis (in seminal vesicle microsomal preparations) and inactivation (using rat caecum 100,000g supernatants) as described in Fig. 1 legend. In both assays plasma was generally tested at final concentrations (v/v) of 0.5, 5.0 and 10.0%.

Low concentrations of rat plasma caused dose-related inhibition of PG synthesis in bovine seminal vesicle microsomes (Fig. 1a) and enhanced the enzymatic inactivation of PGF<sub>2α</sub> in rat caecum supernatants (Fig. 1b). We suggest the provisional term prostaglandin 'reciprocal coupling factor' to designate the

plasma component(s) responsible for these effects. The dose-response curves obtained at the three concentrations tested were usually not linear (with characteristic upward inflections in 25 out of 34 synthesis-inhibition curves and in 29 of 30 metabolism-activation curves), suggesting that the observed effects might be caused by more than one plasma component.

Rat plasma at 5% (v/v) also inhibited the synthesis of bioassayable PG-like material in microsomal systems from four other species (see Fig. 1 legend). That the synthesis inhibition is not due to redirection of endoperoxide breakdown towards other products which cannot be detected by the bioassay (for example, the stable metabolites of prostacyclin or thromboxane A<sub>2</sub>) was shown by incubating bovine seminal vesicle microsomes with radio-labelled arachidonic acid. In the presence of 0.5–10% plasma there was a progressive reduction in the utilization of arachidonic acid and in the amounts of each of the prostanoate products formed. The experiments did not distinguish whether inhibition of synthesis is due to depletion of substrate by binding (perhaps to albumin, as demonstrated previously<sup>8–10</sup>), or to a specific inhibitory effect on the cyclooxygenase component of prostaglandin synthetase.

Enhancement of PGF<sub>2α</sub> inactivation by rat plasma was shown in several other 100,000g supernatants using the radiochemical assay (Fig. 1 legend). To check these results, the time courses of breakdown of prostaglandins E<sub>2</sub> and F<sub>2α</sub> in rat caecum supernatants were also measured by bioassay: as expected, PGE<sub>2</sub> was the better substrate (*t*<sub>1/2</sub> ~ 1.6 min compared with ~ 5.6 min for PGF<sub>2α</sub>), and the rate of disappearance of both PGs was enhanced in the presence of 5% plasma (*t*<sub>1/2</sub> reduced to ~ 0.8 and ~ 2.9 min, respectively).

We wondered whether alterations in the amounts of RCF might contribute to the adaptive changes in apparent levels of PG-synthesizing and metabolizing enzymes which were observed previously in certain animal models of pathophysiological states<sup>1–4</sup>.

Rats were injected subcutaneously (s.c.) for 2 days with prednisolone (5 mg per kg) or vehicle. As expected<sup>1</sup>, apparent levels of PG synthetase and prostaglandinase in kidney, lung, stomach and caecum were reduced and increased, respectively (Fig. 2 legend). Blood samples were collected by cardiac puncture and the plasmas assayed for RCF activity. The dose-response curves in Fig. 2a and b show that the steroid-treated plasmas contained considerably larger amounts of synthesis-inhibiting and inactivation-enhancing activity than those from the control group. The results in Fig. 2a confirm those of Saeed

\* Present address: Department of Pharmacology, Chelsea College, Manresa Road, London SW3 3TW, UK.

**Fig. 1** Demonstration of prostaglandin 'reciprocal coupling factor' (RCF) in rat plasma by assays on PG synthesis (a) and breakdown (b). Synthesis assays: Bovine seminal vesicle microsomes (5 mg ml<sup>-1</sup> lyophilized powder, Miles) were incubated for 30 min at 37 °C in pH 8.0 100 mM Tris-HCl buffer with 10 μg ml<sup>-1</sup> arachidonic acid (Sigma) and 3 mM reduced glutathione to favour conversion to classical PGs, and the amounts of PG-like material assayed after extraction on the isolated rat fundus strip preparation in terms of PGF<sub>2α</sub> equivalents. Bars show mean values ± s.e.m., *n* = 12–16. Breakdown experiments: Freshly prepared 100,000g supernatants of rat caecum homogenized in pH 7.4 50 mM phosphate buffer (final protein concentration 8.6 ± 0.2 mg ml<sup>-1</sup>, *n* = 67) were incubated at 37 °C for 4–10 min as appropriate with 5 mM NAD<sup>+</sup> and 10 μg ml<sup>-1</sup> PGF<sub>2α</sub> containing 0.02–0.05 μCi [9β-<sup>3</sup>H]-PGF<sub>2α</sub> (Radiochemical Centre, specific activity 15 Ci mmol<sup>-1</sup>), and the extent of PGF<sub>2α</sub> breakdown estimated by radiochromatography<sup>19</sup>. Results show mean values ± s.e.m., *n* = 4–8. RCF was found in both plasma and serum, was unaffected by the presence of heparin or if urethane or ether were given to anaesthetize the rats. Both synthesis-inhibiting and breakdown-enhancing properties exhibited similar characteristics: they were completely destroyed after 30 s boiling or pronase digestion (250 U ml<sup>-1</sup>, 16 h at 4 °C), but unchanged by incubation for 5 min at 37 °C or 18 h at 4 °C, by dialysis or by storage at -20 °C and repeated thawing. Most activity was recovered after precipitation by ammonium sulphate and 5 min heating at 60 °C. In Figs 1 and 2 the significance of differences was evaluated by Student's *t*-test, and the following key is used: \* *P* < 0.001, † *P* < 0.002, ‡ *P* < 0.01, § *P* < 0.02, ¶ *P* < 0.05, ¶ not significant. With regard to others systems: 5% (v/v) rat plasma inhibits microsomal PG synthesis in frog skin by 60.8 ± 8.8% (*P* < 0.001), rat kidney 37.3 ± 6.8% (*P* < 0.01), rabbit kidney 59.7 ± 1.5% (*P* < 0.001) and guinea pig kidney 49.3 ± 2.1% (*P* < 0.001) (*n* = 10) and enhances PGF<sub>2α</sub> inactivation in 100,000g supernatants of rat kidney by 54.4 ± 12.9% (*P* < 0.02), rat stomach 18.4 ± 2.2% (*P* < 0.01), rat lung 130.6 ± 22.5% (*P* < 0.01), guinea pig stomach 60.3 ± 15.8% (*P* < 0.001), guinea pig kidney 69.8 ± 11.9% (*P* < 0.01) and guinea pig colon 74.1 ± 6.5% (*P* < 0.001) (*n* = 5).

*et al.*<sup>5</sup> showing that glucocorticoid treatment increases the ability of plasma to inhibit microsomal PG synthesis, but they did not examine organ enzyme levels or test the effects of plasma on PG degradation. A further experiment (not shown) revealed that RCF is released within 30 min of the intra-arterial injection of prednisolone (2.5 mg per kg) as determined by both synthesis-inhibition and metabolism-enhancement assays.

Furthermore, we confirmed (Fig. 2 legend) a previous report that the apparent PG synthetase content in kidneys of rats made diabetic with alloxan is decreased whereas prostaglandinase

activity is elevated<sup>3</sup>. Plasmas collected from alloxan-diabetic rats contained considerably more RCF than those from control animals (Fig. 2c, d).

We anticipated that it might be possible to induce adaptive changes in the opposite direction (increased PG synthesis and decreased breakdown) by treatment of rats with thyroxine. Earlier experiments showed that this reduces prostaglandinase activity in lung and kidney<sup>11</sup>. Lungs, caeca, kidneys and blood samples were taken from rats injected s.c. for 2 days with 200 µg thyroxine. In all organs tested there was a decrease in prostaglandinase and increase in PG synthetase activity (Fig. 2 legend). The plasmas from the thyroxine-treated animals contained markedly less RCF activity than the control plasmas, according to both the microsomal synthetase and the caecum supernatant assays (Fig. 2e, f).

These data show that pathophysiological adaptations in apparent levels of enzymes of the PG system are indeed accompanied by 'appropriate' changes in the amounts of RCF, at least in the three examples studied. To what extent might the plasma factor be responsible for the changes in apparent enzyme activities? At present we cannot exclude the possibility that altered tissue prostaglandinase activities in the cell-free 100,000g supernatants may simply reflect the presence of different amounts of RCF taken up by the tissue or present in the blood entrapped in it, rather than differences in absolute enzyme levels. (Indeed, several authors<sup>12-15</sup> have noted that cytosolic high-speed supernatants are inhibitory to microsomal PG synthesis, perhaps because they contain RCF). It is unlikely that the changes in apparent PG synthetase levels can be explained in terms of altered amounts of RCF because these assays are performed using resuspended microsomes separated from the cytosol, and in some pathophysiological models (such as diabetes, Fig. 2) changes were found in some organs but not in others. Additional experiments (not shown) verified that RCF does not significantly bind to microsomes, thus making it unlikely that the large differences in apparent levels of PG synthetase can be simply due to differences in amounts of adsorbed RCF.

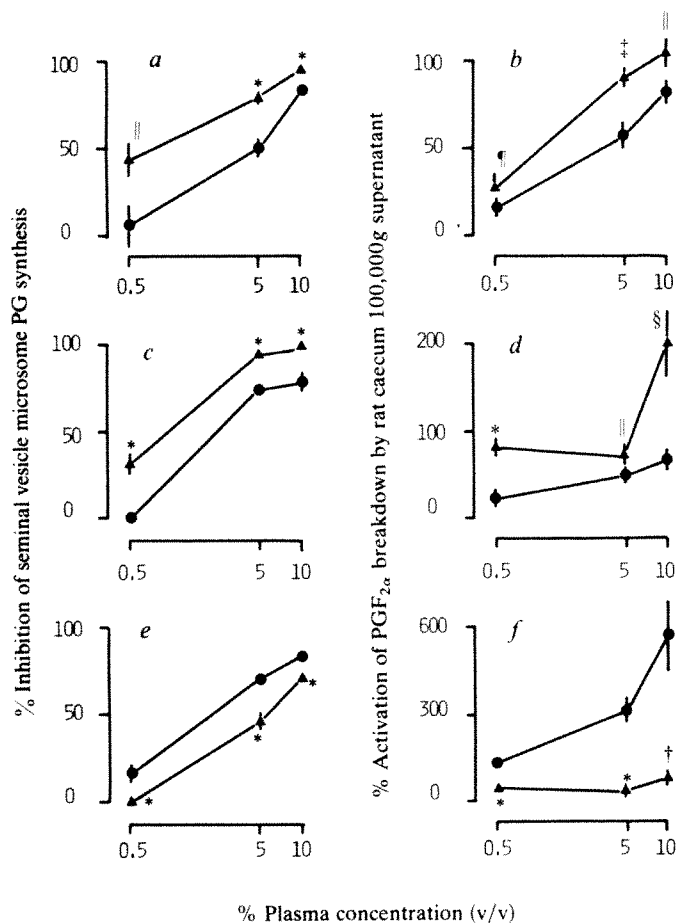

These studies suggest that the activities of the enzymes of the PG system are under sensitive metabolic control and may be susceptible to regulation by rapidly releasable blood-borne factors. Saeed, Collier and co-workers<sup>5,15</sup> have also identified a factor(s) capable of inhibiting microsomal PG synthesis *in vitro* (calling it 'endogenous inhibitor of prostaglandin synthesis'), and others have subsequently shown that serum or plasma may influence the amount or direction of arachidonate metabolism in both intact and broken cell preparations<sup>6,7,16-18</sup>. However, ours is the first demonstration of alterations in plasma factors in model pathophysiological states and shows for the first time that the enzymatic destruction of PGs may also be influenced by blood-borne factors. These results reinforce our view that the functional control and adaptive versatility of the PG system are likely to depend on modulation of breakdown as well as regulation of synthesis.

Finally, it should be noted that the consequences of RCF action, if functionally effective *in vivo*, would be 'anti-homeostatic': thus, high levels would cause or enhance a PG deficiency whereas its absence would favour a PG excess. Either way, this may lead to pathological changes. It is therefore important to discover the identity and mechanism of action of RCF and to find out how and why it is released in the intact animal.

We thank the MRC, Pharmacia AB, May & Baker Ltd and the Central Research Fund of the University of London for financial support, and Drs J. E. Pike, R. L. Jones, H. O. J. Collier and K. Crowshaw for gifts of prostaglandins and seminal vesicles. E. Ramcharan provided technical help.

**Fig. 2** Alterations in rat plasma RCF activity accompany the reciprocal changes in tissue enzyme activities of the PG system in three model pathophysiological states (prednisolone treatment, panels a and b; experimental diabetes, panels c and d; thyroxine administration, panels e and f). Panels a, c and e show inhibition of sheep seminal vesicle microsomal PG synthesis by RCF in rat plasma; panels b, d and f show activation of PGF<sub>2α</sub> breakdown in rat caecum 100,000g supernatants by RCF in rat plasma. ● Denotes plasma from control and ▲ that from treated animals. Points show mean values  $\pm$  s.e.m. (unless smaller than symbol) for 16-20 (synthesis) and 8-10 determinations (breakdown). See Fig. 1 legend for key to statistical evaluation and details of experimental methods. Reciprocal changes in tissue activities of enzymes which synthesize and inactivate PGs were seen after each of the three treatments as shown below. Prednisolone treatment (five Sprague-Dawley rats per group injected s.c. with prednisolone 5 mg per kg or vehicle for 2 days): PG synthetase activity in kidney, caecum, stomach and lung reduced by 45.0  $\pm$  5.0% ( $P < 0.02$ ), 38.0  $\pm$  7.6% ( $P < 0.05$ ), 29.5  $\pm$  12.2% (not significant) and 46.0  $\pm$  5.9% ( $P < 0.05$ ) compared with activity in organs from vehicle-injected animals; prostaglandinase activity increased by 102  $\pm$  9.8% ( $P < 0.001$ ), 122.5  $\pm$  17.0% ( $P < 0.001$ ), 70.3  $\pm$  4.6% ( $P < 0.001$ ) and 57.8  $\pm$  12.9% ( $P < 0.01$ ) compared with control (see also ref. 1). Diabetic rats (five Wistar rats per group injected intravenously with alloxan 50 mg per kg or saline 3 days before death, blood sugar levels  $> 3.5$  mg per ml in diabetic animals): kidney PG synthetase activity reduced by 48.9  $\pm$  5.7% ( $P < 0.002$ ) and prostaglandinase activity increased by 188.8  $\pm$  41.9% ( $P < 0.001$ ), lung activities not changed (see also ref. 3). Thyroxine administration (five Sprague-Dawley rats per group injected s.c. for 2 days with L-thyroxine 200 µg per kg): PG synthetase activity in kidney, caecum and lung enhanced by 169.5  $\pm$  13.2% ( $P < 0.001$ ), 30.4  $\pm$  7.1% ( $P < 0.05$ ), and 304.3  $\pm$  65.4% ( $P < 0.001$ ) compared with activity in control organs, prostaglandinase activity reduced by 48.3  $\pm$  5.1% ( $P < 0.01$ ), 29.9  $\pm$  2.6% ( $P < 0.01$ ) and 40.2  $\pm$  3.2% ( $P < 0.001$ ).

Non-steroidal anti-oestrogens such as tamoxifen, CI 628, nafoxidine and clomiphene, are structurally related synthetic compounds that antagonize the effects of oestrogen on its target tissues<sup>1,2</sup>, and this activity has led to the use of tamoxifen to treat advanced breast cancer<sup>3</sup>. All these compounds inhibit the binding of tritiated oestradiol to cytosol from oestrogen target tissues<sup>2,4-7</sup>, suggesting that anti-oestrogens bind to the oestrogen receptor. This is supported by reports that in the rat uterus<sup>7-10</sup> and dimethyl-benz ( $\alpha$ )-anthracene (DMBA)-induced rat mammary carcinoma<sup>9</sup>, oestradiol and anti-oestrogens bind directly to the same number of saturable binding sites. Furthermore, oestrogens and anti-oestrogens are mutually competitive for binding to these sites<sup>8,10</sup>. It has thus been generally accepted that the anti-oestrogens exert most of their effects through the specific oestrogen receptor. We now report a further high-affinity, anti-oestrogen binding site which may have a role in regulating the effects of non-steroidal anti-oestrogens.

Our evidence comes from comparison of the concentrations of high-affinity, saturable binding sites for oestradiol and anti-oestrogens in the same cytosol preparations, and from competition experiments with tritiated anti-oestrogens. Typical results of saturation analysis experiments with anti-oestrogens are shown in Fig. 1. The binding curves for the four oestrogen target-tissue cytosols were curvilinear (Fig. 1a) but could readily be resolved into a high-affinity, saturable binding site and non-specific binding<sup>11,12</sup> (Fig. 1b). The straight-line Scatchard plot<sup>13</sup> obtained by correction for non-specific binding (Fig. 1b) indicated a single high-affinity site or several saturable sites with similar affinities. No high-affinity sites were detected in the muscle cytosol (Fig. 1a).

Table 1 summarizes the apparent equilibrium dissociation constants ( $K_d$ ) and concentrations ( $C$ ) of high-affinity sites for oestradiol and tamoxifen in cytosol from eight oestrogen target tissues. With the exception of immature rat uterus, all these cytosols contained significantly more anti-oestrogen binding

sites than could be accounted for by oestrogen receptors alone. We have subsequently shown that the anti-oestrogen binding site is also present in immature rat uterus but was masked in the study reported here by a high concentration of oestrogen receptor<sup>14</sup>.

To test the ability of oestradiol to inhibit the binding of tritiated anti-oestrogen to its saturable binding sites, cytosol was

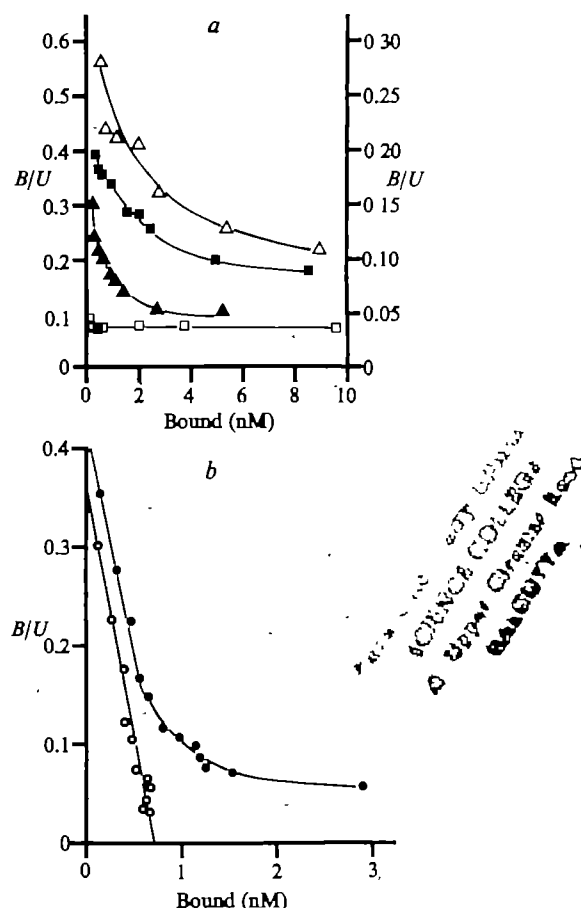

Fig. 1 Scatchard plots of anti-oestrogen binding to human endometrium, rat liver, chick oviduct, rat uterus and chick muscle cytosol. All tissues were homogenized with a Polytron and/or Teflon-glass tissue grinder, in 5-25 volumes (w/v) of 10 mM Tris-HCl buffer, pH 7.4, containing 1.5 mM EDTA and 0.5 mM dithiothreitol. A high-speed cytosol was prepared. Saturation analysis was performed at 4 °C by incubating 100  $\mu$ l of cytosol with a fixed concentration of tritiated tamoxifen (ICI, specific activity 19.5 Ci mmol<sup>-1</sup>) or CI 628 (1.25 nM, Radiochemical Centre, Amersham, specific activity 8-25 Ci mmol<sup>-1</sup>) and increasing concentrations of unlabelled ligand in the range of 1.25 nM-2  $\mu$ M. After 16 h of incubation, protein-bound and unbound ligand were separated by charcoal adsorption (0.5% charcoal for 30 min at 4 °C) and concentrations of bound and unbound ligand were calculated. The apparent equilibrium dissociation constant ( $K_d$ ) and binding site concentration ( $C$ ) of the saturable anti-oestrogen binding sites were calculated from measured bound and unbound ligand concentrations by a non-linear regression analysis technique<sup>11</sup> or by a graphical linearization technique<sup>12</sup>. The former technique was preferred but in the only tissue (chick oviduct) where the techniques were compared on several samples both gave similar results. a, Binding of CI 628 to human endometrium cytosol ( $\Delta$ ) and rat liver cytosol ( $\blacksquare$ ), and binding of tamoxifen to mature rat uterine cytosol ( $\blacktriangle$ ) and chick skeletal muscle cytosol ( $\square$ ). The scale of the left-hand ordinate applies to human endometrium only. b, Binding of CI 628 to chick oviduct cytosol before ( $\bullet$ ) and after ( $\circ$ ) correction for nonspecific binding. Tritiated CI 628 was greater than 97% pure at dispatch but was a 40:60 mixture of the *cis* and *trans* isomers. Tritiated tamoxifen was 88-90% pure on dispatch and was pure *trans* isomer. Purity was monitored continually by thin-layer chromatography and did not differ significantly from that at dispatch during the course of the experiments.

Experimental procedures are described in Fig. 1 legend. Binding-site concentration (*C*) is expressed as nmol of oestradiol or tamoxifen specifically bound per litre of reaction mixture, which was a twofold dilution of the cytosol. Data are presented as the mean ± s.e.m. or the mean plus range in parentheses.

\* With oestrogen receptors.

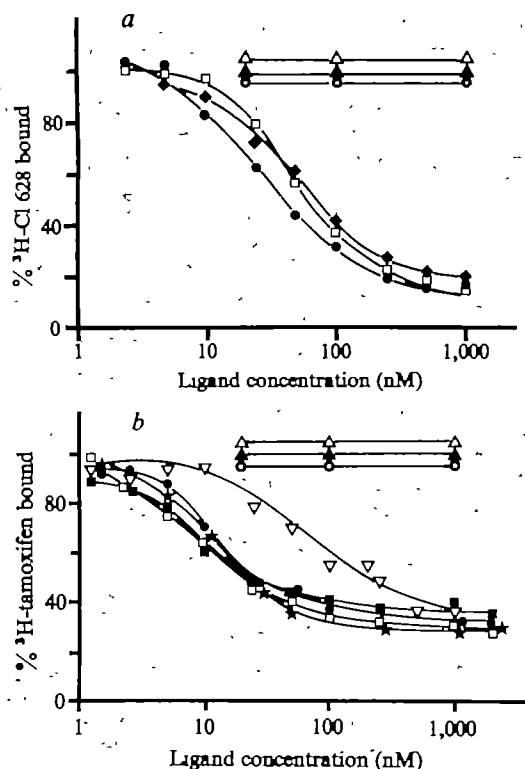

incubated with tritiated CI 628 or tamoxifen and increasingly higher concentrations of oestradiol or anti-oestrogen. Figure 2 shows that the degree of inhibition by oestradiol varied with the tissue. With immature rat uterine cytosol, inhibition was complete<sup>7–10</sup>, whereas in mature rat uterus and chick oviduct it was partial (Fig. 2). In human mammary carcinoma that had oestrogen receptors, oestradiol did not inhibit anti-oestrogen binding, whereas only non-specific binding occurred in chick muscle (Fig. 2). This can probably be explained by the relative affinities and concentrations of oestrogen and anti-oestrogen binding sites in cytosols, because those factors govern the amount of tritiated anti-oestrogen bound to the oestrogen receptor and thus the proportion of label displaced by oestradiol. For example, using data presented in Table 1 and elsewhere<sup>15</sup>, we calculated that only 5–7% of tritiated tamoxifen was bound to the oestrogen receptor in the mammary carcinoma cytosol, so that oestradiol could not displace significant amounts of label.

To assess the ligand specificity of the anti-oestrogen binding site we used cytosol from MCF 7 cells grown in 10% fetal calf serum because the relative concentration of saturable anti-oestrogen binding sites and oestrogen binding sites is greater than 50:1 (L.C.M. and R.L.S., unpublished data). As a result, essentially no tritiated anti-oestrogen was bound to the oestrogen receptor and competition curves represent the inhibition of binding of tritiated anti-oestrogen to anti-oestrogen binding site alone. Tamoxifen, CI 628 and nafoxidine all inhibited the binding of tritiated CI 628 to its saturable binding site (Fig. 3a), whereas natural and synthetic oestrogens, androgens, and progestins did not (Fig. 3a), indicating that the high-affinity anti-oestrogen binding site was not a sex steroid hormone receptor. To show that these results were not due to a contaminant of tritiated CI 628, similar experiments were performed with tritiated tamoxifen (Fig. 3b). Again anti-oestrogens (tamoxifen, CI 628, ICI 47,699, enclomiphene and *N*-desmethyltamoxifen) inhibited binding whereas the same steroids were ineffective.

The structural requirements for binding to the anti-oestrogen binding site are different from those for the binding of these anti-oestrogens to the oestrogen receptor. The *cis* isomers of tamoxifen and clomiphene (ICI 47,699 and zuclophene) have only 5–10% of the affinity of the *trans* isomers for the oestrogen receptor<sup>16</sup> but both *cis* and *trans* tamoxifen have similar affinities for the anti-oestrogen binding site (Fig. 3b). Studies with 4-hydroxytamoxifen, a metabolite with 5–10 times the affinity of tamoxifen for the oestrogen receptor<sup>17,18</sup>, showed that aromatic monohydroxylation had no effect on the affinity of tamoxifen for the anti-oestrogen binding site (A.M.W. and R.L.S., unpublished data). In contrast, demethylation in the

**Fig. 2** Competition of oestradiol and anti-oestrogens (CI 628 or tamoxifen) for anti-oestrogen binding sites in chick oviduct, rat uterus, human mammary carcinoma with oestrogen receptors and chick muscle cytosol. Aliquots of cytosol were incubated for 16 h at 4 °C with 1.25 nM tritiated CI 628 or tamoxifen and increasingly high concentrations of unlabelled oestradiol or anti-oestrogen (tamoxifen or CI 628). Protein-bound radioactivity was separated by charcoal adsorption and the data were plotted as d.p.m. tritiated anti-oestrogen bound against log of the added ligand concentration. Results for chick oviduct (diamonds), mature rat uterus (circles), oestrogen receptor-positive human mammary carcinoma (squares) and chick skeletal muscle cytosols (triangles) are illustrated. Binding of tritiated anti-oestrogen in the presence of increasingly high concentrations of unlabelled oestradiol or anti-oestrogen are represented by solid and open symbols, respectively. Tamoxifen was the anti-oestrogen in the experiment with mammary carcinoma cytosol whereas in the other three experiments CI 628 was the anti-oestrogenic ligand. The protein concentrations of the cytosols are listed in Table 1 and the oestrogen receptor concentrations in fmol per mg protein were: chick oviduct, 112; mature rat uterus, 297; human mammary carcinoma, 119; and chick muscle, 0. For clarity the ordinate for the chick oviduct data has been expanded twofold, that is  $B_0$  for chick oviduct = 1,500 d.p.m.

**Fig. 3** Specificity of the saturable anti-oestrogen binding site in MCF 7 human mammary carcinoma cell cytosol. Tritiated CI 628 (a) or tamoxifen (b), cytosol and increasingly high concentrations of: tamoxifen (●), CI 628 (□), nafoxidine (◆), enclomiphene (★), ICI 47,699 (■), *N*-desmethyltamoxifen (▽); androgens: testosterone, 5 $\alpha$ -dihydrotestosterone, R1881 (○), oestrogens: oestradiol, oestrone, diethylstilboestrol (▲), and progestins: progesterone, R5020 (△), were incubated for 16 h at 4°C and the protein-bound radioactivity was measured after adsorption on charcoal. Data are presented as the amount of tritiated anti-oestrogen bound in the presence of added ligand, expressed as a percentage of tritiated anti-oestrogen bound in the absence of added ligand against log of the concentration of added ligand.

alkylaminoethoxy side chain had little effect on receptor binding<sup>19</sup> but markedly reduced the affinity for the anti-oestrogen binding site (compare tamoxifen with *N*-desmethyltamoxifen in Fig. 3b).

These data (Figs 1–3, Table 1), demonstrating an excess of high-affinity, saturable anti-oestrogen binding sites over oestrogen receptor sites and the inability of oestradiol to compete for all these sites, are evidence for an anti-oestrogen binding site. The site has a high affinity ( $K_d = 3$ –10 nM) for CI 628 and tamoxifen and is saturable at nanomolar concentrations of the drugs. It shows a surprising degree of specificity, binding a series of structurally related synthetic non-steroidal anti-oestrogens but not several steroid hormones (Fig. 3). There is also an indication of tissue specificity in that the site was present in all oestrogen target tissues studied but not in human mammary carcinoma that lacked oestrogen receptors<sup>15</sup> nor in rat plasma and skeletal muscle. In addition we have shown that it is a protein, for binding activity can be destroyed by trypsin but not by lipase, RNase or DNase. The observation that its concentration changes during the oestrous cycle in rats<sup>20</sup> suggests that this intracellular binding protein is under hormonal control.

Our data are consistent with anti-oestrogen binding to the cytoplasmic oestrogen receptor as well as to the anti-oestrogen binding site. Indeed the competition curves illustrated in Fig. 2 and elsewhere<sup>7</sup> demonstrate partial or complete inhibition of anti-oestrogen binding by oestradiol. We believe that anti-oestrogens bind to two saturable binding components *in vivo* which often cannot be resolved *in vitro* because of their relative

concentrations and affinities and the range of ligand concentrations used. However, experiments with human mammary carcinoma containing high titres of oestrogen receptor generated curves which could be resolved<sup>11</sup> into two saturable binding components (oestrogen receptor and anti-oestrogen binding site) in addition to non-specific binding<sup>21</sup>.

We have no evidence that this binding site mediates the effects of anti-oestrogen on target tissues. The possibility that it has a natural ligand and mediates the antagonistic effects of the drugs whereas agonist effects are mediated through the oestrogen receptor warrants investigation. In any case, the affinity and concentration of the anti-oestrogen binding site are such that it must bind a significant proportion of the drugs *in vivo* and so may regulate the amounts of anti-oestrogen available for binding to the oestrogen receptor.

We thank ICI, Warner Lambert/Parke-Davis, Merrell and Upjohn for anti-oestrogens, and Professor M. H. N. Tattersall for interest, encouragement and critical comment.

## Stimulus–secretion coupling in rabbit neutrophils is not mediated by phosphatidylinositol breakdown

S. Cockcroft, J. P. Bennett & B. D. Gomperts

Department of Experimental Pathology,  
School of Medicine, University College London, University Street,  
London WC1E 6JJ, UK

In common with other cells which use intracellular  $Ca^{2+}$  to mediate specific cell function, when rabbit neutrophils are stimulated with specific agonists the rate of metabolism of phosphatidylinositol (PI) increases<sup>1–3</sup>. This is normally measured as the incorporation of radioactive phosphate or inositol into PI, but these reactions are presumed to be secondary processes following the initial breakdown of pre-existing PI to diacylglycerol<sup>4</sup>. The radioactive labels are incorporated during the stepwise resynthesis of PI via phosphatidic acid (PA). It has been suggested that in the sequence of biochemical events, starting with the binding of the ligand to a receptor, and finally resulting in the expression of cellular activity, the breakdown of PI is an early event immediately directed by activation of the receptor<sup>1,4</sup>. This could then control the increase in cytoplasmic  $Ca^{2+}$  and other processes dependent on this. Here we report an analysis of the temporal relationship between these phospholipid changes and cell stimulation. Our evidence suggests that in neutrophils, PI breakdown and PA labelling are both consequences and not causes of a rise in intracellular  $Ca^{2+}$ .

**Fig. 1** Time course of  $\beta$ -glucuronidase secretion from rabbit neutrophils stimulated with  $10^{-8}$  M fMet-Leu-Phe (○) and  $5 \times 10^{-6}$  M ionomycin (●). Neutrophils were obtained from the rabbit peritoneal cavity 4–6 h after infusion of 250 ml 0.1% glycogen in saline<sup>3</sup>. They were suspended at  $4 \times 10^7$  cells  $\text{ml}^{-1}$  in a buffered salt solution, pH 7.5, comprising 137 mM NaCl, 2.7 mM KCl, 1 mM  $\text{MgCl}_2$ , 1.8 mM  $\text{CaCl}_2$ , 20 mM HEPES, 5.6 mM glucose and 1 mg  $\text{ml}^{-1}$  bovine serum albumin. The cells were incubated at 37 °C for 45 min. After addition of cytochalasin B ( $5 \mu\text{g ml}^{-1}$ ), the cells were immediately added to fMet-Leu-Phe or ionomycin contained in small volumes of buffer. Samples containing  $\sim 4 \times 10^7$  cells were quenched into ice-cold saline at the times indicated. The secreted  $\beta$ -glucuronidase released into the extracellular fluid was measured as previously described<sup>3</sup>. There was no detectable increase in the released  $\beta$ -glucuronidase in the absence of added ligands.

As agonists for neutrophil activation, we have used the synthetic tripeptide formylmethionyl-leucyl-phenylalanine (fMet-Leu-Phe) and ionomycin, which is a  $\text{Ca}^{2+}$ -carrying ionophore<sup>5</sup>. Activation of neutrophils normally results in an increase in cell motility, but in the presence of cytochalasin B ( $5 \mu\text{g ml}^{-1}$ ), the cells secrete lysosomal enzymes (we measure  $\beta$ -glucuronidase) and the motile functions are suppressed<sup>6</sup>. Chemotaxis and secretion are known to be different expressions of the same cell-surface receptors<sup>7</sup>, and we have previously demonstrated that cytochalasin B does not significantly affect the binding of fMet-Leu-Phe to its receptor and the induced  $\text{Ca}^{2+}$  fluxes; nor does it alter the extent of PI labelling<sup>3</sup>.

Figure 1 shows the time course of  $\beta$ -glucuronidase secretion from cytochalasin B-treated neutrophils due to fMet-Leu-Phe ( $10^{-8}$  M) and ionomycin ( $5 \times 10^{-6}$  M). The secretion due to the receptor-directed tripeptide is 90% complete within 10 s of adding the ligand, and so any early events which could dictate or modulate the course of the secretory process must be expressed within this time. Secretion due to the ionophore is characterized by a delay of about 20 s and is complete within about 60 s.

Figure 2 shows the changes in the radioactivity of PA and PI during 120 s following the addition of fMet-Leu-Phe to neutrophils which had been preincubated for 45 min in the presence of  $^{32}\text{P}$ -phosphate to label phospholipids and the ATP pool. The radioactivity in these cells was quenched by direct addition to a mixture of chloroform/methanol (1:2), and the lipids were extracted and separated by TLC. Within 10 s of the addition of the ligand, the radioactivity of PI had declined by 30% whereas that of PA had increased slightly. Thereafter, the radioactivity in both lipids increased due to the incorporation of  $^{32}\text{P}$  from ATP into the intermediates for PI resynthesis. In other experiments (data not shown), in which cells prelabelled with  $^3\text{H}$ -glycerol were used, the radioactivity of PI declined to a similar extent within 10 s. In this case, the ensuing increase in radioactivity was not observed, because  $^3\text{H}$ -glycerol can only enter PI as a consequence of *de novo* synthesis and, unlike  $^{32}\text{P}$ -phosphate, is not incorporated during the resynthesis cycle<sup>1</sup>.

Although the time dependence of PI breakdown certainly justifies its designation as an early event, our previous work showed that PI resynthesis (labelling) is unrelated to  $\text{Ca}^{2+}$  movements and the stimulation of secretion<sup>2</sup>. Secretion due to fMet-Leu-Phe will occur in the absence of extracellular  $\text{Ca}^{2+}$  due to mobilization of  $\text{Ca}^{2+}$  from intracellular sources<sup>8</sup>, but in these circumstances we found that PI labelling does not occur<sup>2</sup>. Table 1 shows that this is also true of PI breakdown. In addition, we show that when  $\text{Ca}^{2+}$  is introduced into the cell using ionomycin, secretion is accompanied by PI breakdown, and we have found that both responses are  $\text{Ca}^{2+}$  dependent. In this case, PI breakdown follows a slower time course similar to that of the ionomycin-stimulated secretion illustrated in Fig. 1 (results not shown).

We conclude that, in neutrophils, breakdown of PI is not essential for  $\text{Ca}^{2+}$  mobilization and secretion. Ionomycin and the receptor-directed agonist were equally effective in causing PI breakdown. Although the breakdown of PI is rapid, it is apparently a consequence and not a cause of the elevation of  $\text{Ca}^{2+}$  in the cytosol. Implicit in the results presented (Table 1) is the possibility that the concentration of intracellular  $\text{Ca}^{2+}$  required to induce PI breakdown might be higher than that needed for secretion. These results also exclude the recently suggested<sup>9,10</sup> possibility that PA generated during resynthesis of PI could be the intrinsic ionophore which permits  $\text{Ca}^{2+}$  movement into agonist-stimulated cells. In neutrophils the appearance of PA is a late event and furthermore (unlike secretion), is dependent on extracellular  $\text{Ca}^{2+}$  (see Table 1).

There is a close correlation between cell activation processes mediated by an elevation of cytosol  $\text{Ca}^{2+}$  and the stimulation of PI metabolism<sup>1,4,11</sup>. The possibility that PI breakdown could precede and thus regulate the fluxes of  $\text{Ca}^{2+}$  which lead to

**Fig. 2** Time course of the changes in radioactivity of PI and PA after addition of fMet-Leu-Phe to neutrophils. Neutrophils ( $4 \times 10^7$  cells  $\text{ml}^{-1}$ ) were incubated at 37 °C for 45 min with  $50 \mu\text{Ci ml}^{-1}$   $^{32}\text{P}$ -P<sub>i</sub>. Four samples (1 ml) were then quenched directly into 3.75 ml of chloroform/methanol (1:2) (zero time control) and the remainder of the cells were immediately added to fMet-Leu-Phe (final concentration  $10^{-8}$  M) contained in a small volume. Samples were taken and quenched at the times indicated. The lipids were extracted<sup>13</sup> and separated by TLC as previously described<sup>14</sup>. The lipids were identified by staining with iodine vapour and by autoradiography. The spots containing PI and PA were scraped into vials and the radioactivity measured by liquid scintillation counting. Open symbols indicate zero time control, mean  $\pm$  s.e.m.,  $n = 4$ ; PA =  $1,890 \pm 110$  c.p.m.; PI =  $2,470 \pm 100$  c.p.m. There was no detectable increase in the radioactivity of these two lipids in control samples during the 2-min period of incubation. A similar kinetic pattern of phospholipid changes was obtained when cytochalasin B-treated neutrophils were used, and the cells quenched with ice-cold saline. In 12 independent experiments, using fMet-Leu-Phe at  $10^{-8}$  M, we found that at 10 s breakdown of labelled PI was  $26 \pm 2\%$  and the increment in PA labelling was  $32 \pm 5\%$ .

**Table 1** Effects of  $\text{Ca}^{2+}$  on agonist-induced secretion and changes in radioactivity of  $^{32}\text{P}$ -labelled phosphatidylinositol and phosphatidic acid

a, Effect of  $\text{Ca}^{2+}$  on secretion and changes in radioactivity of PI and PA after 10-s exposure of cytochalasin B-treated neutrophils to fMet-Leu-Phe. b, Secretion and changes in the radioactivity of PI and PA after 45-s exposure of cytochalasin B-treated neutrophils to ionomycin +  $\text{Ca}^{2+}$ . Neutrophils ( $4 \times 10^7$  cell  $\text{ml}^{-1}$ ) were incubated for 45 min in a  $\text{Ca}^{2+}$ -free buffer (EGTA 10  $\mu\text{M}$ ) containing  $^{32}\text{P}$ . After the addition of cytochalasin B (5  $\mu\text{g ml}^{-1}$ ), three pairs of samples (1 ml) were transferred in succession to tubes containing agonist (fMet-Leu-Phe  $10^{-8}$  M or ionomycin  $5 \times 10^{-6}$  M) and buffer, with or without  $\text{Ca}^{2+}$  (1.8 mM); these were quenched after 10 s (fMet-Leu-Phe) or 45 s (ionomycin) by addition of 5 ml of ice-cold saline. The whole operation was complete within 2 min. After centrifugation at 4  $^{\circ}\text{C}$ , the supernatant was sampled for estimation of  $\beta$ -glucuronidase and the cell lipids were extracted and analysed as described in Fig. 2 legend.  $\text{Ca}^{2+}$  had no effect on secretion and phospholipid changes in the absence of fMet-Leu-Phe. Results are expressed as mean  $\pm$  s.e.m.,  $n=3$ . Concentration of  $\text{Ca}^{2+}$  in  $\text{Ca}^{2+}$ -free buffer (measured with a  $\text{Ca}^{2+}$  electrode) was less than 5  $\mu\text{M}$ .

activation has been a popular concept because in many of the earlier systems studied, PI responses seemed to be independent of extracellular  $\text{Ca}^{2+}$  (ref. 2). If breakdown of PI has a universal role in cell activation processes, our results with neutrophils, and those of others with platelets<sup>12</sup>, indicate that this is not in the regulation of  $\text{Ca}^{2+}$  fluxes.

## The possible functional significance of phosphatidylethanolamine methylation

Dennis E. Vance & Ben de Kruijff\*

Department of Biochemistry, University of British Columbia, Vancouver, British Columbia, Canada V6T 1W5

The conversion of phosphatidylethanolamine to phosphatidylcholine was first reported in rat liver microsomes by Bremer and Greenberg<sup>1</sup>. The reaction requires three successive methylations of the ethanolamine moiety by *S*-adenosylmethionine. The highest activity for this enzyme has been found in liver microsomes and the enzyme from rat liver was recently solubilized and partially purified<sup>2</sup>. Although the activity is highest in liver, it is the minor pathway in this tissue for the synthesis of phosphatidylcholine<sup>3</sup>. The enzyme has recently been identified in bovine adrenal medulla<sup>4</sup> and reports exist on the activity of phosphatidylethanolamine methyltransferase in erythrocyte ghosts<sup>5</sup>, reticulocyte ghosts<sup>6,7</sup> and mammary gland membranes<sup>8</sup>. In view of the relatively minor importance of the

methylation pathway in phosphatidylcholine biosynthesis in liver, we were intrigued by the reports of significant physiological changes attributed to phospholipid methylation<sup>9–11</sup>. Calculations reported here show that this enzymatic activity in reticulocytes, erythrocytes and mammary gland membranes is 0.1% of that observed in liver microsomes. Furthermore, in conditions where marked changes in microviscosity of the erythrocyte membrane were observed, only extremely small amounts of phosphatidylethanolamine were methylated<sup>9</sup>. For these and other reasons, there is considerable doubt that methylation of phosphatidylethanolamine could account for the many physiological responses attributed to this activity.

Table 1 compares the activity for *N*-methylation of phosphatidylethanolamine in rat liver microsomes with the highest activity reported for several other membrane preparations. The activity in the microsomes from adrenal medulla is 100-fold lower than in liver microsomes and 1,000-fold lower in the three other membrane preparations. In the presence of exogenously added phosphatidyl-*N*-monomethylethanolamine, the activity in liver microsomes and in erythrocyte ghosts was 0.58 (ref. 2) and 0.0003 nmol (Fig. 1 of ref. 5)  $^3\text{H}$ -methyl transferred per min per mg protein, respectively. In view of the very low enzymatic activities of the last three membrane preparations listed in Table 1, we question whether or not the activity is associated with these membranes. Perhaps the activity is due to cellular impurities in the preparation.

Because such low methylation activity was observed with the erythrocyte membrane, we decided to calculate the number of molecules of phosphatidylethanolamine methylated during these incubations. In one reported experiment, erythrocyte ghosts were incubated for 1 h at 37  $^{\circ}\text{C}$  with 100  $\mu\text{M}$  *S*-adenosylmethionine<sup>9</sup>. During this incubation 4.4 pmol of phosphatidylethanolamine were methylated per mg of membrane protein. The ratio of protein to lipid in rat erythrocytes is 1.1 (ref. 10). Thus, there would be 0.91 mg lipid per mg protein, and on a molar ratio half of this lipid (0.62 mg) is polar lipid<sup>10</sup>. Most, if not all, of the polar lipid is phospholipid. The phospholipids of the rat erythrocyte include 47.5% phosphatidylcholine and 21.5% phosphatidylethanolamine<sup>11</sup>. From these data and the assumption of 750 and 800 as the respective molecular weights of phosphatidylethanolamine and phosphatidylcholine, we can calculate that rat erythrocyte membranes contain 173,000 pmol of phosphatidylethanolamine and 362,000 pmol of phosphatidylcholine per mg protein. During the incubation described above, 2.0 pmol of phosphatidyl-*N*-monomethylethanolamine, 1.2 pmol of phosphatidyl-*N,N*-dimethylethanolamine and 1.2 pmol of phosphatidylcholine were apparently formed<sup>9</sup>. Thus, 0.0012% of the phosphatidylethanolamine was converted to the monomethyl derivative. Of the phosphatidylcholine molecules present, only 0.00033% were formed via methylation of phosphatidylethanolamine in the 1-h incubation. Despite these extremely small amounts of lipids converted or formed, a relatively large change in microviscosity from 1.62 to 1.09 P was observed in the same experiment. Therefore, it seems highly unlikely that the changes in membrane microviscosity could have been caused by methylation of phosphatidylethanolamine. Some other explanation must be sought for the observed changes in microviscosity. This conclusion is supported by the studies of Schroeder *et al.*<sup>12</sup> with LM cells. There was no change in the fluidity of the membranes or membrane lipid (as measured by several different probes) when the polar head group of the phospholipid in the cell or subcellular membranes was altered by more than 50%.

Another area of concern in the reports on methylation of phosphatidylethanolamine is the extremely small amounts of  $^3\text{H}$  incorporated into the lipids. There is a serious possibility that the  $^3\text{H}$  radioactivity originates from contaminating compounds in the *S*-adenosyl-L-[Me- $^3\text{H}$ ]methionine. For instance, in the

**Table 1** Comparison of various enzymatic activities for methylation of phosphatidylethanolamine

| Source of enzyme   | Enzyme activity<br>(nmol <sup>3</sup> H-methyl<br>transferred per<br>min per mg protein) |
|--|--|
| Rat liver microsomes (ref. 2)                            | 0.45   |
| Bovine adrenal medulla microsomes<br>(Table 1 of ref. 4) | 0.0040   |
| Rat erythrocyte ghosts (Table 2 of ref. 5)               | 0.0005   |
| Rat reticulocyte ghosts (Fig. 3 of ref. 6)               | 0.0001   |
| Mammary gland membranes (Table 3 of<br>ref. 8)           | 0.0003   |

Information in parentheses indicates the source of the data.

experiment reported in Table 1 of ref. 5, only 0.05% of the radioactivity is incorporated into phosphatidyl-*N*-monomethyl-ethanolamine. The radiopurity of the *S*-adenosyl-*L*-[Me-<sup>3</sup>H]methionine as supplied by New England Nuclear is approximately 99% by the time this compound is used. Thus, the amount of contaminating <sup>3</sup>H-labelled compounds is many times higher than the actual amount of <sup>3</sup>H incorporated. Therefore, it is essential that for each system quantitative data are provided which show that the only radioactivity incorporated in the membrane is that of <sup>3</sup>H-methyl in the polar head group of the methylated phospholipid. In the reports<sup>6-8,13-17</sup> that suggest a link between physiological effects and phospholipid methylation, such studies are lacking. In addition, these experiments are subject to the same criticisms as detailed above. Hence, we are not convinced that methylation of phosphatidylethanolamine is related to any physiological response or change in membrane fluidity.

## Reply from J. Axelrod and F. Hirata

Section on Pharmacology, Laboratory of Clinical Science,  
National Institute of Mental Health, Bethesda, Maryland 20205

From papers published in our own and other laboratories, Vance and de Kruijff make calculations showing that phospholipid methylation activities observed in a variety of tissues and cells are very low. They then argue that because of these low enzyme activities, all the reported findings on the association between phospholipid methylation and biological responses are due to an impurity in *S*-adenosyl-Me-[Me-<sup>3</sup>H]methionine.

Vance and de Kruijff have not provided any experimental evidence for this assumption.

The reports on the methylation of membrane lipids satisfy the biochemical criteria of enzymatic reactions<sup>1-4</sup>: (1) no significant activity in a heated preparation, (2) saturated substrate concentration-velocity curves, (3) pH dependency, (4) subcellular localization, (5) sensitivity to proteolytic enzymes, (6) stimulation by exogenous phospholipid substrates and cofactors and (7) competitive inhibition by *S*-adenosylhomocysteine. All the methylated lipids arising from *S*-adenosyl-[Me-<sup>3</sup>H]methionine were identified by TLC with several solvent systems, chemical and enzymatic degradation and column chromatography with ion-exchange resin of products from chemical degradation<sup>1,2,4-6</sup>. These observations exclude the possibility of measuring the impurities as phospholipid methylation. The alternative explanation is that an impurity of <sup>3</sup>H-*S*-adenosylmethionine has the capacity to transmethyrate an acceptor lipid and an exceedingly high affinity ( $K_m$  in  $10^{-9}$  M range) for the reaction. In experiments using intact cells (mast cells<sup>5,7</sup>, basophils<sup>8</sup>, neutrophils<sup>9</sup>, astrocytoma cells<sup>10</sup> and lymphocytes<sup>11</sup>), [Me-<sup>3</sup>H]methionine, a precursor of *S*-adenosylmethionine, was used for the assay of phospholipid methylation. Therefore, the impurity should also be formed in intact cells from methionine and the transfer of the methyl group should be blocked by methyltransferase inhibitors such as *S*-adenosylhomocysteine and its analogues<sup>7-11</sup>. It would be extremely unlikely that an as yet unidentified artefact would have all of the above properties.

Vance and de Kruijff make the sweeping claim (without providing any evidence) that "... we are not convinced that methylation of phosphatidylethanolamine is related to any physiological response or change in membrane fluidity". Experiments have shown a dose-dependent increase of phospholipid methylation, with the methyl donor, *S*-adenosylmethionine, which is associated with a decrease in membrane viscosity of red blood cells<sup>12</sup>. When the methyltransferase inhibitor, *S*-adenosylhomocysteine is added with *S*-adenosylmethionine, changes in membrane viscosity are abolished with a concomitant inhibition of phospholipid methylation. It has been previously shown that extremely low concentrations of prostaglandins (a few molecules per cell) cause changes in membrane viscosity<sup>13</sup>. Therefore, the fact that small amounts of phospholipid are methylated is no indication that phospholipid methylation is not involved. The amounts of phospholipids methylated after the stimulation of  $\beta$ -adrenergic receptors in reticulocytes<sup>14</sup> and C<sub>6</sub> astrocytoma<sup>10</sup> are calculated to be 30 molecules per receptor molecule, a value which is almost equivalent to that of the annulus lipids around Ca<sup>2+</sup>-ATPase, a typical transmembrane protein<sup>15</sup>. Such changes in lipid composition may be sufficient to change the fluidity and to enhance the coupling of receptor to adenylate cyclase. As 1,6-diphenyl-1,3,5-hexatriene, a fluorescence probe we used for measuring membrane fluidity, is preferentially embedded in the boundary of lipid domains<sup>16</sup>, local and bulk changes of membrane fluidity cannot be separated by measuring its anisotropy. The order of potency for several agonists to increase methylation is similar to their ability to generate cyclic AMP<sup>10,14</sup>. Increased methylation could be blocked by  $\beta$ -adrenergic antagonists. These observations are consistent with the previous reports that increasing membrane fluidity with vaccenic acid facilitates coupling of receptor to adenylate cyclase<sup>17</sup> and that decreasing fluidity with cholesterol reduces the coupling<sup>18</sup>. Almost all the changes in phospholipid methylation reported were shown to be receptor mediated ( $\beta$ -adrenergic<sup>10,14</sup>, concanavalin A<sup>5,11</sup>, chemotactic peptide<sup>9</sup>, benzodiazepine<sup>10</sup> and IgE receptors<sup>7,10</sup>). Because receptors occupy only a tiny fraction of the cell surface, it would require only small amounts of methylating enzymes clustered near the receptor to produce changes in phospholipid composition. Note that phosphatidylcholine formed by transmethylation contains the major portion of arachidonic acid although transmethylation is only a minor pathway for the phosphatidylcholine synthesis compared with the CDP-choline pathway<sup>19,20</sup>. Arachidonic acid

(a fatty acid of great importance for cell function) is liberated by receptor stimulation<sup>8,9,11</sup>, suggesting a close coupling of receptor, methyltransferases and phospholipases and a rapid turnover of methylated phospholipids.

When cells are labelled with [ $^3\text{H}$ ]methionine, the methyl group is mainly incorporated into the phospholipid fraction via *S*-adenosylmethionine after receptor stimulation<sup>7</sup>. The subsequent physiological responses such as lymphocyte mitogenesis<sup>11</sup>, histamine release from mast cells<sup>5,7</sup> and basophils<sup>8</sup>

and leukocyte chemotaxis<sup>9</sup> can be inhibited by treatment with 3-deazaadenosine and its analogues, which are intracellularly transformed to *S*-adenosylhomocysteine analogues, inhibitors of transmethylation reactions<sup>21</sup>. By treating cells with 3-deazaadenosine and its analogues, phospholipid methylation but not the transmethylation of nucleotides and proteins is inhibited, in the conditions used by us. All these experiments show the close association between receptor-mediated phospholipid methylation and physiological responses.

## Reduced somatostatin-like immunoreactivity in cerebral cortex from cases of Alzheimer disease and Alzheimer senile dementia

Peter Davies\*, Robert Katzman† & Robert D. Terry\*

Departments of \*Pathology and of Neuroscience, and of †Neurology and of Neuroscience, Albert Einstein College of Medicine, 1300 Morris Park Avenue, The Bronx, New York 10461

Both Alzheimer's disease and senile dementia of the Alzheimer type (AD/SDAT) are progressive dementias characterized neuropathologically by the presence in the cerebral cortex of numerous neurofibrillary tangles and neuritic plaques<sup>1</sup>. We use the abbreviation AD/SDAT to denote all such cases, irrespective of age of onset<sup>2</sup>. Studies of neurotransmitter-related parameters in autopsied brain tissues from patients with AD/SDAT have, to date, been confined to five putative transmitter systems. Acetylcholine-releasing neurones seem to be most markedly and consistently affected, as judged by the extensive reductions in choline acetyltransferase (ChAT) and acetylcholinesterase activities that have been reported<sup>3-6</sup>. Despite numerous studies, there is no consistent evidence for the involvement of neurones releasing dopamine, noradrenaline, serotonin, or  $\gamma$ -aminobutyric acid in AD/SDAT<sup>4</sup>, nor for loss of muscarinic cholinergic receptors<sup>7</sup>. Thus, the involvement of cholinergic neurones in AD/SDAT seems to be specific. However, the possible involvement of neurones using other chemicals as transmitters has yet to be explored. The recent recognition of the existence of so-called 'peptidergic neurones' in the mammalian brain (for review see ref. 8) and the availability of radioimmunoassay (RIA) techniques for studying these peptides, have led us to begin a systematic investigation of neuropeptides in autopsied brain tissue from cases of AD/SDAT, and from neurologically normal individuals. We report here results obtained with a RIA for somatostatin, showing that somatostatin-like immunoreactivity in the cerebral cortex is reduced in tissue from AD/SDAT patients.

Synthetic somatostatin (Peninsula) was coupled to bovine serum albumin as described by Arimura *et al.*<sup>9</sup>, and an antiserum was raised in rabbits. The serum was used in RIA at a final dilution of 1:48,000 with <sup>125</sup>I-labelled tyr<sup>1</sup>-somatostatin as tracer (NEN; 2,200 mCi mmol<sup>-1</sup>). The presence of 1  $\mu\text{g}$  per

tube of substance P, insulin, proinsulin, glucagon, Met-enkephalin, thyrotropin releasing hormone, gastrin, cholecystokinin octapeptide or neurotensin did not interfere with the assay. The limit of sensitivity of the assay was about 5 pg of synthetic somatostatin, the intra-assay variability was  $\pm 7\%$  and inter-assay variation  $\pm 12\%$ .

Samples of right cerebral cortex were obtained at autopsy from 12 neurologically normal individuals (mean age 74 yr, range 40-101 yr) within 24 h of death (mean delay death to autopsy 11 h, range 3-24 h). The areas studied were mid-frontal gyrus, superior temporal gyrus, inferior parietal cortex and hippocampus. Neuropathological examination of left cerebral hemispheres revealed no gross or microscopic abnormalities. Similar samples were obtained from 12 cases of AD/SDAT (mean age 74 yr, range 49-92 yr; mean delay 10 h, range 2-16 h). Neuropathologically, all 12 AD/SDAT cases showed many neurofibrillary tangles and neuritic plaques in sections of frontal and parietal cortex, and in hippocampus, with no evidence of cerebrovascular disease, Parkinson's disease or other abnormality.

Extracts of brain tissues were made by boiling in 2 M acetic acid, homogenization and centrifugation at 10,000g for 30 min. Aliquots of supernatants were freeze-dried and residues were re-dissolved in phosphate-buffered saline, pH 8.2, containing 0.1% bovine serum albumin. The efficiency of extraction of <sup>125</sup>I-labelled somatostatin added to frozen tissue samples was 89%. The slopes of displacement curves produced by the addition of serial dilutions of extracts of brain regions were not significantly different from those produced by addition of various amounts of synthetic somatostatin. Although this indicates immunochemical similarity between material in brain extracts and synthetic somatostatin, it does not prove identity. Our preliminary studies with gel filtration have so far failed to

Table 1 Choline acetyltransferase activity in cerebral cortex samples from normal and AD/SDAT cases

|                         | Normal            |    |         | AD/SDAT           |    |        |
|-------------------------|-------------------|----|---------|-------------------|----|--------|
|                         | Mean $\pm$ s.e.m. | n  | Range   | Mean $\pm$ s.e.m. | n  | Range  |
| Hippocampus             | 575 $\pm$ 77      | 11 | 203-960 | 168 $\pm$ 31      | 10 | 58-367 |
| Frontal cortex          | 394 $\pm$ 59      | 12 | 91-751  | 48 $\pm$ 9        | 11 | 7-112  |
| Parietal cortex         | 305 $\pm$ 49      | 12 | 112-681 | 35 $\pm$ 8        | 12 | 7-77   |
| Superior temporal gyrus | 428 $\pm$ 69      | 12 | 97-673  | 49 $\pm$ 16       | 12 | 9-164  |

Choline acetyltransferase activity is expressed as nmol acetylcholine produced per h per 100 mg protein. Values for all regions of AD/SDAT cases are significantly lower than those of normals ( $P < 0.01$ ).

**Table 2** Somatostatin-like immunoreactivity in cerebral cortex samples from normal and AD/SDAT cases

|                         | Normal     |    |           | AD/SDAT    |    |           |
|-------------------------|------------|----|-----------|------------|----|-----------|
|                         | Means.e.m. | n  | Range     | Means.e.m. | n  | Range     |
| Hippocampus             | 3.56±0.40  | 10 | 0.84–5.35 | 0.95±0.04  | 8  | 0.77–1.10 |
| Frontal cortex          | 2.99±0.39  | 12 | 1.11–5.79 | 0.72±0.15  | 12 | 0.17–1.45 |
| Parietal cortex         | 3.28±0.70  | 12 | 1.27–8.89 | 1.47±0.40  | 12 | 0.07–3.83 |
| Superior temporal gyrus | 3.05±0.39  | 12 | 0.75–5.04 | 0.97±0.30  | 12 | 0.00–2.86 |

Somatostatin-like immunoreactivity is expressed as ng per mg protein. Values for hippocampus, frontal cortex and superior temporal gyrus are significantly lower in AD/SDAT than in normal tissue ( $P < 0.01$ ), as are those in parietal cortex ( $P < 0.05$ ).

reveal evidence for the presence of high molecular weight (>3,000) putative precursors of somatostatin in acetic acid extracts of human cerebral cortex. We therefore refer to immunoreactive material in human brain as somatostatin-like immunoreactivity. Choline acetyltransferase activities from these cases were determined on separate samples of the same brain regions by methods previously described<sup>3</sup>.

In agreement with our own and other published data, all four regions of AD/SDAT brains investigated showed marked, statistically significant reductions in the activity of ChAT (see Table 1). The reductions in ChAT reported here, and by one of us previously, are larger than those reported by others. One reason for this may be the ages of the patients chosen as controls, as we have discussed elsewhere<sup>3</sup>. A second factor may be our selection of only severe cases of AD/SDAT; that is, of only those cases with many plaques and tangles in both the cerebral cortex and hippocampus. The amounts of somatostatin-like immunoreactivity in all four regions of AD/SDAT brains were also significantly below those found in brains from normal individuals (Table 2). In the hippocampus, both ChAT activity and somatostatin-like immunoreactivity were reduced by about the same extent, 70.8% and 73.3%, respectively. It is possible that these two parameters are within the same neuronal structure: co-existence of peptide and amine transmitters in a single neurone has been demonstrated in other systems<sup>8</sup>. However, there is no other evidence for the presence of somatostatin in cholinergic terminals in the hippocampus. In the cortical regions studied, there is a greater loss of ChAT activity than of somatostatin-like immunoreactivity. The greatest loss of somatostatin-like immunoreactivity seems to occur in frontal cortex (75.9%), and the least in parietal cortex (55.2%). In both these regions the ChAT activity is reduced by almost 90%.

We have considered the possibility that the reduced somatostatin-like immunoreactivity found in the AD/SDAT cases might result from factors other than the disease. However, we have been unable to find any evidence of correlation between the amount of somatostatin-like immunoreactivity and the age of the patient, either in the control or AD/SDAT groups. Similarly, there was no correlation between the somatostatin-like immunoreactivity concentration and the delay period between death and autopsy. Because of the large number of different drug treatments administered to both the controls and the AD/SDAT cases before death, we have been unable to determine whether any one such treatment might be of particular significance.

Thus, our data seem to indicate the involvement of a second putative neurotransmitter system in AD/SDAT, and provide the first evidence for loss of a neuronal peptide in AD/SDAT cases. Efforts must now be directed towards characterizing the immunoreactive material in both normal and AD/SDAT brain. We do not yet know whether or not the loss of somatostatin-like immunoreactivity has functional significance to the patient with AD/SDAT. Further clinical and biochemical work is needed before this most important point can be clarified.

Our thanks to Aurora Thompson for technical assistance. This work was supported in part by NIH grants AG-01066, NS-03356 and NS-02255, and by a gift from A. and B. Condiolti.

**Much current attention focuses on the renin-angiotensin system in relation to mechanisms controlling blood pressure and renal function. Recent demonstrations (ref 1, ref. 2 and refs therein) that angiotensin-converting enzyme inhibitors show promising clinical antihypertensive properties have been of particular interest. We now report on the design of a novel series of substituted N-carboxymethyl-dipeptides which are active in inhibiting angiotensin-converting enzyme at nanomolar levels. We suggest that these compounds are transition-state inhibitors and that extensions of this design to other metalloendopeptidases merit further study.**

The biological profile of three of these inhibitors was assessed in rats and dogs by the antagonism of the pressor response to angiotensin I. High converting-enzyme inhibitory activities (at doses as low as 2.3 µg per kg) were demonstrated after intravenous (i.v.) administration. Given orally (p.o.) in dogs these three compounds showed good activities with a duration of action of at least 6 h at doses of 0.3 mg per kg. This particularly long duration of action and their apparent specificity may make these compounds useful in the treatment of hypertension.

Angiotensin-converting enzyme (peptidyl dipeptide hydrolase, EC 3.4.15.1) generates the powerful vasoconstrictor substance angiotensin II by removing the C-terminal dipeptide from the precursor decapeptide angiotensin I (ref. 3). The enzyme also inactivates the vasodilating substance bradykinin<sup>4</sup>. That angiotensin-converting enzyme inhibitors might display useful antihypertensive properties has been demonstrated clinically by the nonapeptide SQ 20,881 (ref. 1) and more recently by many studies<sup>2</sup> on the orally active angiotensin-converting enzyme inhibitor captopril (SQ 14,225)<sup>5</sup>. The latter structure, D-3-mercapto-2-methylpropanoyl-L-proline (resulting from work by the Squibb group) inhibits the enzyme with a reported IC<sub>50</sub> of  $2.3 \times 10^{-8}$  M (ref. 6).

**Table 1** *In vitro* converting-enzyme inhibitory activities of *N*-carboxymethyl-L-alanyl-L-proline, derivatives and analogues\*

Converting enzyme was prepared from fresh citrated hog plasma by the method of Dorer *et al.*<sup>17</sup> up to fraction 'B', followed by chromatography on Sephadex G-200 and collection of the fractions of highest specific activity. This enzyme was chloride-dependent, 90% inhibited by EDTA at  $1 \times 10^{-4}$  M and yielded His-Leu from angiotensin I as determined by TLC. Assays adapted from the method of Piquilloud *et al.*<sup>18</sup> were conducted in the following manner. Test compounds were dissolved at  $5 \times 10^{-3}$  M in 0.05 M borate-phosphate buffer, pH 8.0, 0.17 M in NaCl. Further dilutions were made with this buffer. To 100  $\mu$ l of each test-compound solution was added 100  $\mu$ l each of  $3.7 \times 10^{-4}$  M substrate solution Cbz-Phe-His-[<sup>14</sup>C-Leu]-OH, 5,500 c.p.m. per tube and converting-enzyme solution diluted from stock so as to give approximately 1,200 c.p.m. in the control supernatant after incubation. The final concentration of substrate was  $1.23 \times 10^{-4}$  M.  $K_m$  in this assay system was between 1 and  $2 \times 10^{-4}$  M. The reaction was incubated 1 h at 30 °C, then terminated by the addition of 1 ml of a 40% (settled solids) suspension in 0.05 M borate buffer of benzoylated DEAE (BD) cellulose (Schwarz-Mann 100–200 mesh, defined), pH 11 or 20% BD Sephadex (Biorad) in 0.05 M borate buffer, pH 7.7. Unreacted substrate was bound to the BD adsorbant and separated from supernatant by filtration through a cotton-plugged Sarpette (size 102/2, Walter Sarstedt). The entire supernatant plus a 0.5-ml buffer wash of the BD residue was collected in a scintillation vial. Counting was done in 10 ml PCS (Amersham Searle) for 10 min. Minus-enzyme blanks were run through the assay and subtracted from each control and test count. IC<sub>50</sub> values (concentration for 50% inhibition) were determined by linear regression of logit against log concentration over a 20–80% inhibition range.

\* Except where indicated, compounds were synthesized by the reductive condensation of  $\alpha$ -ketoacids or esters with dipeptides and were assayed without the separation of diastereomers. All compounds were characterized by satisfactory mass spectra and NMR data and by TLC on silica-gel plates.

† This compound was prepared by the alkylation of L-alanyl-L-proline in aqueous solution at 85 °C by the portion-wise addition of chloroacetic acid over 1 h with maintenance of pH 8–9.

‡ Diastereomers were separated by chromatography on 200–400 mesh XAD-2 polystyrene resin (Rohm and Haas) using 95:5 (v/v) 0.1 M aqueous NH<sub>4</sub>OH-methanol and were crystallized from water. Compound 6a (eluted first) [ $\alpha$ ]<sub>D</sub><sup>25</sup> =  $-67.0^\circ$  C (0.1 M HCl); compound 6b (eluted second) [ $\alpha$ ]<sub>D</sub><sup>25</sup> =  $-101.6^\circ$  C (0.1 M HCl). Compound 6a: Analyses calculated for C<sub>18</sub>H<sub>24</sub>N<sub>2</sub>O<sub>5</sub>·1/2H<sub>2</sub>O: C, 60.40; H, 7.05; N, 7.84. Found: C, 60.60; H, 7.01; N, 7.79.

§ Compound 7 was prepared from  $\epsilon$ -benzyloxycarbonyl-L-lysine ethyl ester and *N*-pyruvoyl-L-proline in dry tetrahydrofuran. Sodium cyanoborohydride was added to this mixture after it had been stirred at room temperature for 4 h with powdered no. 4A molecular sieves. Protecting groups were removed by saponification of the ethyl ester with 0.1 M NaOH overnight followed by hydrogenolysis of the benzyloxycarbonyl group in 1:1 ethanol-water over 10% Pd/C catalyst at 40 p.s.i. Diastereomers were not separated.

|| Hydrocinnamaldehyde was reductively condensed with L-alanyl-L-proline using sodium cyanoborohydride in aqueous ethanol.

¶ This salt was precipitated from an acetonitrile solution of *N*-(1-ethoxycarbonyl-3-phenylpropyl)-L-alanyl-L-proline (mixed diastereomers) using a half-molar equivalent of maleic acid. Repeated recrystallization from acetonitrile afforded pure compound 10 [ $\alpha$ ]<sub>D</sub><sup>25</sup> =  $-42^\circ$  (CH<sub>3</sub>OH). Analyse calculated for C<sub>24</sub>H<sub>22</sub>N<sub>2</sub>: C, 58.53; H, 6.55; N, 5.69. Found: C, 58.49; H, 6.53; N, 5.61. As even traces of 6a in this sample would give significant inhibition, the IC<sub>50</sub> may overestimate its potency.

# Compound 10 is also designated MK-421.

\*\* Compound 11 was prepared from *N*-pyruvoyl-L-proline and L-proline benzyl ester using sodium cyanoborohydride in methanol. The benzyl group was subsequently removed by hydrogenolysis using 10% Pd/C in aqueous ethanol at 40 p.s.i. Diastereomers were not separated.

†† Compound 12 was prepared from d1-2,4-dimethylglutaric acid<sup>19</sup> which as its anhydride was reacted with L-proline benzyl ester in CH<sub>2</sub>Cl<sub>2</sub>. The benzyl group was removed by hydrogenolysis and the diastereomers separated by successive chromatography over LH-20 using CH<sub>3</sub>OH followed by HPLC on a Whatman Partisil-10 ODS-2 preparative column using H<sub>2</sub>O:CH<sub>3</sub>CN:HOAc (75:25:1).

The most common side effects accompanying the clinical use of captopril are rashes and loss of taste both of which usually clear on withdrawal or reduction of dose<sup>2</sup>. As similar side effects are observed with penicillamine<sup>7</sup>, we looked for potent specific inhibitors of angiotensin-converting enzyme lacking a mercapto function and characterized by weak chelating properties. We report here the design of such compounds illustrated by generic formula (I).

These substituted *N*-carboxymethyl-dipeptides are conveniently prepared by the reductive coupling of  $\alpha$ -ketoacids or esters to the amino terminus of suitably protected dipeptides utilizing sodium cyanoborohydride or hydrogenation with palladium-on-carbon or Raney nickel. Typically, 1.42 g of 2-oxo-4-phenylbutyric acid was dissolved in 5 ml of water by adjusting the pH to 6.8 with 50% NaOH. L-Alanyl-L-proline (0.27 g) was then added and the solution treated with 0.28 g of sodium cyanoborohydride in 5 ml of water. After stirring at room temperature overnight, 35 ml of Dowex 50 X-2, 50–100 mesh on the acid cycle, was added to absorb the product and destroy any residual sodium cyanoborohydride. The slurry was then added to a column containing 20 ml of Dowex 50 and

| 22  | L-arginine                 | L-proline          | $6.4 \times 10^{-9}$ M |

See Table 1 legend for methods.

\* The data reported are for the more active diastereomer which was separated from the mixture of isomers by chromatography on a 200–325 mesh XAD-2 polystyrene resin column using 0.1 M NH<sub>4</sub>OH as the eluant.

† Compound 21a was isolated from the mixture of diastereomers (compound 21) by initial LH-20 chromatography using methanol followed by chromatography on a jacketed 200–400 mesh XAD-2 polystyrene resin column at 50°C utilizing 3% acetonitrile in 0.1 M NH<sub>4</sub>OH as the eluant. The more active diastereomer 21a eluted first and was crystallized from methanol/ethyl acetate;  $[\alpha]_D^{25} = -23.3^\circ$  (CH<sub>3</sub>OH). Analyses calculated for C<sub>21</sub>H<sub>31</sub>N<sub>3</sub>O<sub>5</sub>·H<sub>2</sub>O: C, 59.56; H, 7.85; N, 9.92. Found: C, 59.56; H, 7.88; N, 9.77.

neutrals eluted with methanol and water. The product was eluted with 8 × 50 ml of 2% pyridine in water, and the product-rich cuts were lyophilized to yield 0.43 g of *N*-(1-carboxy-3-phenylpropyl)-L-alanyl-L-proline as a mixture of two diastereomers. Alternatively some compounds have been synthesized as indicated in Tables 1 and 2 legends by reductive coupling of amino acids to pyruvoyl-L-proline or via dipeptide alkylation using the appropriate α-haloacid.

A new asymmetric centre is created when ketoacids or esters are reductively coupled to dipeptides to yield structures of formula (I). These diastereomers can be separated by chromatography. For example, compound 6 after chromatography on milled XAD-2 polystyrene resin with 0.1 M NH<sub>4</sub>OH in 95:5 (v/v) water/methanol yielded diastereomers 6a and 6b differing in their *in vitro* potencies by roughly 700-fold. The more active diastereomer 6a was determined by X-ray diffraction to have the *S, S, S* configuration (the structure was determined by Dr J. P. Springer).

**Fig. 1** The p.o. converting-enzyme inhibitory activity of captopril (■), inhibitors 6a (▲), 10 (□) and 21a (○) at 0.3 mg per kg p.o. in unanaesthetized dogs. Dogs were fasted overnight. The per cent inhibition of the pressor response to angiotensin I, 150 ng per kg i.v. over 6 h is shown. Each compound was evaluated in at least three dogs. The animals were not challenged with angiotensin I between 1 and 2 h. Thus the possibility exists that captopril's peak effect could have occurred between 1 and 2 h.

We synthesized over 200 variants of structure (I) to explore requirements for tight inhibitor binding. Representative structures are shown in Tables 1 and 2. In apparent parallel with studies on captopril analogues<sup>5,6,8</sup>, we found that cyclic imino acids such as proline confer particularly high activity at the dipeptide's carboxyl terminus. Consistent with the enzyme's specificity<sup>9–11</sup> imino acids in the position penultimate to the carboxyl terminus were not compatible with high inhibitory activities (for example, compounds 11 and 19). Note that both hydrophobic and basic substituents could be incorporated at R<sub>1</sub> and R<sub>2</sub> in highly active analogues. Inhibitory specificity was demonstrated by the inactivity of compounds 6a and 10 when tested at  $3.3 \times 10^{-5}$  M against renin, plasmin, trypsin, chymotrypsin and carboxypeptidases A and B (E.H.U. and T.C.V., details to be reported elsewhere). Note also that the amino acid analogue *N*-(1-carboxy-3-phenylpropyl)-L-alanine inhibited carboxypeptidase A and angiotensin-converting enzyme by less than 10% at  $1 \times 10^{-5}$  M.

Studies on the mechanism of action of these inhibitors are in progress. Inhibition by a chelating effect to remove Zn<sup>2+</sup> from the active site of the enzyme can be ruled out because the *in vitro* enzyme inhibitory activity of these compounds is unaffected by added Zn<sup>2+</sup>. Indeed, their chelating ability for Zn<sup>2+</sup> is only comparable to that of α-amino acids<sup>12</sup>. For example, log K<sub>1</sub> for compound 6a is 4.9. The kinetics of inhibition by compounds 6a and 21a are consistent with a competitive mechanism (H. Bull, E. H. Cordes and N. Thornberry, to be reported elsewhere). Furthermore, the importance of the NH in structure (I) for inhibitory potency is suggested by the marked reduction in activity resulting from the replacement of the NH in compound 2 by a CH<sub>2</sub> group (compound 12). This finding is consistent with the enzyme's well-documented<sup>9,11</sup> requirement for an —NH at the corresponding position in peptide substrates. We suggest that our inhibitors should be broadly classified as transition-state inhibitors (ref. 13 and refs therein). In this interpretation

**Table 3** *In vivo* comparisons of selected converting-enzyme inhibitors including captopril

| Compound  | IC <sub>50</sub> *<br><i>In vitro</i> | ID <sub>50</sub> (rat)<br>i.v. (μg per kg) | ID <sub>50</sub> (dog)<br>i.v. (μg per kg) |
|-----------|---------------------------------------|--|--|
| Captopril | $2 \times 10^{-8}$ M                  | 60.5<br>(51.3–71.6)                        | 80<br>(67–97)                              |
| 6a        | $1.2 \times 10^{-9}$ M                | 8.2<br>(6.6–10.6)                          | 6.4<br>(4.7–8.0)                           |

| 21a       | $1.2 \times 10^{-9}$ M                | 2.3<br>(1.7–3.0)                           | 6.5<br>(5.6–7.6)                           |

The ability of the compounds to inhibit the pressor response to angiotensin I (see text for doses) was determined in mecamylamine (1.0 mg per kg i.v.)-pretreated anaesthetized (Dial-urethane, 0.8 mg per kg intraperitoneally) rats and in anaesthetized (vinbarbital sodium, 60 mg per kg) normotensive dogs. These doses of angiotensin I in rats and dogs caused an approximately equivalent pressor response (50–60 mm Hg). The ID<sub>50</sub> (dose of inhibitor which produced a 50% inhibition of angiotensin I) was computed in both rats and dogs by increasing the doses of the antagonist in logarithmic intervals and in a cumulative manner. In rats and dogs the ID<sub>50</sub> varied with the dose of angiotensin I. Rubin *et al.*<sup>20</sup> found considerably lower values for captopril's ID<sub>50</sub>, for example, 15 (13–18) μg per kg i.v. in anaesthetized rats. The reason for the higher ID<sub>50</sub> in the present experiments may reflect differences in anaesthetic, presence of ganglionic blockade and interval between doses. Our *in vitro* results with captopril are consistent with those reported by Ondetti *et al.*<sup>5</sup> regarding the inhibition of converting enzyme (see above) and the potentiation of bradykinin in which we determined an AC<sub>50</sub> of 2.4 nM in the guinea pig ileum. The ID<sub>50</sub> values in rats and dogs were also computed in a nmol per kg basis. In rats for captopril, compounds 6a, 10 and 21a, the following values were computed: 253.1, 23.5, 37.2 and 5.7 nmol per kg, respectively. In the dog, the corresponding ID<sub>50</sub> values in nmol per kg were as follows: captopril, 334.7; compound 6a, 18.4; compound 10, 738.6; and compound 21a, 16.0. The values in parentheses are the 95% confidence intervals.

\* See Tables 1 and 2. The IC<sub>50</sub> for captopril varied from  $3.4 \times 10^{-8}$  M to  $2.9 \times 10^{-9}$  M with the most of the determinations at  $2 \times 10^{-8}$  M.

transition state-like geometry is attained at the scissile CONH locus via the  $\text{CHCO}_2\text{H}$  and  $\text{NH}$  groups. Cumulative binding contributions are provided by the  $\text{CO}_2\text{H}$ ,  $\text{NH}$  and  $\text{R}_1$  groups as indicated in the analogue studies. It remains to be determined if the  $\text{NH}$  is protonated while bound to the enzyme, thus contributing a potential electrostatic interaction.

These compounds were evaluated for their ability to antagonize the pressor effect of angiotensin I administered i.v. to rats and dogs. Doses of angiotensin I were selected which represented the midpoint of their respective dose-response curves. In anaesthetized rats this was 100 ng per kg i.v., and it was 600 ng per kg i.v. in anaesthetized dogs. In conscious dogs, angiotensin I was administered at 150 ng per kg i.v. Data for three of our inhibitors are summarized in Table 3 and compared with captopril. Clearly compounds 6a, 10 and 21a were highly active by the i.v. route in rats. The same was true in dogs except for compound 10 whose ester functionality was found to be hydrolysed by dog liver homogenates but poorly so by dog plasma. Hydrolysis of compound 10 in rat plasma was rapid. (Hydrolysis of  $^{14}\text{C}$ -(Proline UL) compound 10 to compound 6a was estimated by incubation of  $10^{-5}\text{ M}$  compound 10 with undiluted plasma or a 1:5 homogenate of liver in  $5\text{ mM}$   $\text{NaHCO}_3$ . The reaction was stopped at various times by acidification with  $\text{HCl}$  and after isolation using XAD-4 resin the proportion of compounds 6a to 10 was determined by TLC (Quantum LQDF developed with  $n\text{-BuOH}:\text{HOAc}:\text{H}_2\text{O}$ , 4:1:1) and by the degree of inhibition of angiotensin-converting enzyme.)

All three compounds were orally active in rats and dogs. Comparative p.o. converting-enzyme inhibitory activities in dog are shown in Fig. 1. Compounds 6a, 10 and 21a displayed high potency in inhibiting the blood pressure response to angiotensin I and all had a long duration of action. Detailed pharmacological studies further demonstrating the p.o. and i.v. activities of some of these compounds and their antihypertensive properties will be reported elsewhere<sup>14,15</sup>.

Clinical studies now in progress<sup>16</sup> with compound 10 (MK-421) should help to determine if converting-enzyme inhibitors lacking a mercapto function have advantages in respect to side effects. More importantly, we believe that our angiotensin-converting enzyme inhibitors have important design implications for the synthesis of inhibitors of other metallopeptidyl carboxypeptidases and possibly of metalloendopeptidases more generally. In our design a  $\text{CO}_2\text{H}$ , an  $\text{NH}$  and an  $\text{R}$  group are arranged in tetrahedral geometry at the locus of the scissile amide group. Their binding energies in concert replace the  $\text{Zn}^{2+}$ /sulphydryl interaction which is a required feature of captopril<sup>3,6,8</sup>.

We thank Drs C. Hoffman, S. Michelson and H. Schwam for isolations of angiotensin-converting enzyme, and Dr J. A. McCauley for determination of the zinc metal stability constant.

## <sup>3</sup>H-apomorphine labels both dopamine postsynaptic receptors and autoreceptors

Pierre Sokoloff, Marie-Pascale Martres & Jean-Charles Schwartz

Unité 109 de Neurobiologie, Centre Paul Broca de l'INSERM, 2ter, rue d'Alésia, 75014 Paris, France

Evidence points to the existence of multiple classes of dopamine (DA) receptor in mammalian brain which can be distinguished by their pharmacological specificities and localizations, and by the actions they mediate<sup>1</sup>. Among them, dopaminergic autoreceptors are regulatory receptors presumed to be present in the membrane of the DA neurones themselves, and believed to mediate an inhibition of these neurones' activity, either at nerve endings or on cell bodies<sup>2-4</sup>. However, the pharmacology of autoreceptors remains to be established because attempts to characterize autoreceptors by <sup>3</sup>H-ligand binding techniques have produced controversial data. Thus Seeman and co-workers stated that <sup>3</sup>H-apomorphine selectively labels autoreceptors<sup>5,7</sup>, whereas Creese *et al.* concluded that this ligand selectively labels postsynaptic DA receptors<sup>8,9</sup>. In addition, large differences in the capacity and drug specificity of <sup>3</sup>H-apomorphine receptor sites in rat striatum have been reported<sup>10-13</sup>. We demonstrate here that <sup>3</sup>H-apomorphine labels two classes of DA receptor, distinguishable using domperidone, a selective DA antagonist<sup>14-17</sup>. Lesion studies indicate that they correspond to a certain class of postsynaptic receptor and to autoreceptors, respectively. Each of these classes displays a clearly distinct pharmacological specificity for antipsychotics and DA agonists.

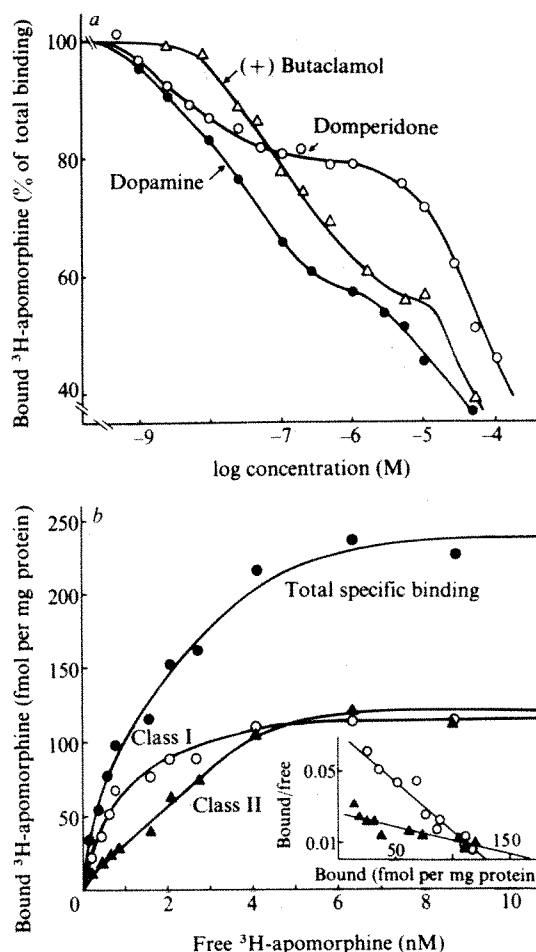

Total binding of <sup>3</sup>H-apomorphine was studied at 6 nM in the presence of increasing concentrations of DA, (+)butaclamol (an antipsychotic drug) or domperidone. As shown in Fig. 1a, DA and (+)butaclamol displayed monophasic inhibition curves up to concentrations of 1 and 10  $\mu\text{M}$  respectively. At these concentrations, a small but reproducible plateau was observed allowing definition of the specific binding (45% of total binding) in conditions similar to those used by others<sup>6,8,10,18</sup>. In contrast, domperidone inhibited this specific binding in a clearly biphasic manner, and a wide plateau appeared between approximately 50 nM and 2  $\mu\text{M}$ . This allowed definition of two pharmacologically distinct classes of <sup>3</sup>H-apomorphine binding site: class I, comprising sites recognized by low concentrations of domperidone ( $\text{IC}_{50} = 5\text{ nM}$ ), and class II, composed of sites poorly recognized by domperidone ( $\text{IC}_{50} \sim 10\text{ }\mu\text{M}$ ).

Saturation of these two classes of binding site by <sup>3</sup>H-apomorphine in increasing concentrations was studied separately—class I sites by determining the fraction of binding inhibited by 200 nM domperidone, and class II sites by determining the binding which occurred in the presence of 200 nM domperidone and was inhibited by 1  $\mu\text{M}$  dopamine (Fig. 1b). Both classes of binding site distinguished by domperidone are characterized by high affinities for <sup>3</sup>H-apomorphine ( $K_d$  0.9 and 2.6 nM), and the capacity of each one amounts to about 120 fmol per mg protein (7 pmol per g tissue).

Lesion data show that these two classes of site are located on different populations of striatal neurones (Table 1). Class I sites seem to be mostly, if not exclusively, present on intrinsic neurones, as the drop in their binding capacity after kainate lesion (-57%) is the same as the reduction occurring in the activity of glutamate decarboxylase, a marker of striatal  $\gamma$ -aminobutyric acid neurones. In addition, the number of class I sites is significantly enhanced after 6-hydroxydopamine (6-OHDA)-induced degeneration of afferent DA

**Fig. 1**  $^3\text{H}$ -Apomorphine binding to rat striatal particulate fraction. The dissected tissues (40–50 mg) from Sprague-Dawley rats (C. River, 200–250 g) were gently sonicated (Ultrasons-Annemasse; sonotrode  $d = 4.5$  mm) at  $4^\circ\text{C}$  in 2 ml 50 mM Tris-HCl buffer pH 7.4 (in 15 ml borosilicated glass tubes). After a three-fold dilution, the homogenate was centrifuged (5,000 g min) and the supernatant diluted two-fold and centrifuged (200,000 g min) in 12 ml cellulose nitrate test tubes. The pellet was resuspended in 2 ml Tris-HCl buffer using a glass-glass homogenizer (Dounce, clearance 70–120  $\mu\text{m}$ ) and incubated for 12 min at  $37^\circ\text{C}$  in a metabolic shaker (140  $\text{cm}^{-1}$ ). After fivefold dilution and centrifugation (200,000 g min), the particulate fraction was resuspended with the Dounce homogenizer in 2 ml freshly prepared 50 mM Tris-HCl buffer pH 7.4 containing 120 mM NaCl, 5 mM KCl, 1 mM  $\text{CaCl}_2$ , 1 mM  $\text{MgCl}_2$ , 0.1% ascorbic acid and 10  $\mu\text{M}$  pargyline ('Tris-ions buffer'). The suspension was briefly sonicated (4 s) before use. In preliminary experiments, we checked that this procedure for tissue preparation led to an almost complete elimination of  $^3\text{H}$ -DA added before homogenization. In the binding assay, 200  $\mu\text{l}$  freshly prepared tissue suspension were preincubated for 20 min at  $30^\circ\text{C}$  in polystyrene test tubes. Incubations were initiated by addition of 200  $\mu\text{l}$  Tris-ions buffer containing  $[8, 9\text{-}^3\text{H}]\text{apomorphine}$  (30.6 Ci  $\text{mmol}^{-1}$ , NEN) and various drugs, and were carried on for 30 min at  $30^\circ\text{C}$ . Drugs were dissolved in either Tris-ions buffer or 0.01–0.05% lactic acid and diluted into glass tubes with Tris-ions buffer. Lactic acid at the final concentration used did not interfere with the binding. Incubations were stopped by dilution with 3 ml ice-cold Tris-ions buffer followed by rapid filtration under vacuum (0.2–0.4 bar) through Whatman GF/B filters. Tubes were rinsed with 3 ml ice-cold Tris-ions buffer and the filters were washed with  $2 \times 5$  ml of the same slowly delivered buffer. After drying the filters, the radioactivity was counted by liquid scintillation spectrometry in 12 ml toluene-Triton X-100-PP-POP (21-11-16.5 g-0.45 g) at an efficiency of 45%. Binding on filters represented less than 0.5% of the total radioactivity. *a*, Inhibition by three dopaminergic agents. Striatal particulate fractions were incubated in the presence of 6 nM  $^3\text{H}$ -apomorphine and dopamine (●), (+) butaclamol ( $\Delta$ ) or domperidone ( $\circ$ ) in increasing concentrations. Values are expressed in per cent of total binding ( $523 \pm 73$  fmol per mg protein) and represent the mean of 6–8 determinations performed in two separate experiments. s.e.m. of these values (not shown) were less than 3% of total binding. *b*, Saturability and Scatchard analysis (inset). Total specific binding (●) was that inhibited by 1  $\mu\text{M}$  dopamine. Binding to class I sites ( $\circ$ ) was that inhibited by 200 nM domperidone. Binding to class II sites ( $\Delta$ ) was that occurring in the presence of 200 nM domperidone minus that in the presence of 1  $\mu\text{M}$  dopamine. At 6 nM  $^3\text{H}$ -apomorphine, radioactivity bound to the tissue was about 3,500 c.p.m. without inhibiting drug, 2,700 c.p.m. in the presence of 200 nM domperidone and 1,900 c.p.m. in the presence of 1  $\mu\text{M}$  dopamine. Total specific binding as well as binding to class I or II sites increased linearly with protein level between 0.1 and 0.3 mg per incubation. Values are the means of 3–10 determinations performed in three independent experiments. Analysis of these data by an iterative computing method based on the least squares<sup>32</sup> gave the following parameters:  $(B_{\text{max}})_I = 131 \pm 12$  fmol per mg protein,  $(K_d)_I = 0.92 \pm 0.24$  nM,  $(nH)_I$  (Hill constant) =  $0.95 \pm 0.17$  for the first class and  $(B_{\text{max}})_{II} = 151 \pm 32$  fmol per mg protein,  $(K_d)_{II} = 2.64 \pm 1.18$  nM,  $(nH)_{II} = 1.17 \pm 0.30$  for the second; values are in good agreement with those obtained by Scatchard plot analysis.

neurones. On the other hand, the number of class II sites is not affected by kainate lesions but is significantly reduced after two kinds of selective lesion of DA neurones (Table 1). The changes observed after degeneration of DA neurones consist of a reduction in the number of class II sites and a rise in the number of class I sites, with no change in the affinity of domperidone for either class of site. Thus, when  $^3\text{H}$ -apomorphine binding in striata of 6-OHDA-lesioned animals (eight rats in two separate experiments) was displaced by domperidone in increasing concentrations, a curve (not shown) similar to that in Fig. 1a was obtained. It also exhibited a large plateau whose height on the ordinate was reduced compared to the control.

The highly heterogeneous but more or less parallel distribution of the two classes of site among the various regions of rat brain reflects DA terminal distribution and thus supports the idea that DA receptors are labelled in both cases<sup>19</sup>.

The drug specificity of sites I and II was established in conditions allowing selective labelling of each class (Table 2). For class I sites, which displayed the highest affinity for  $^3\text{H}$ -apomorphine, a low ligand concentration was used (0.8 nM). For class II sites, inhibitory potencies were established in the presence of 6 nM  $^3\text{H}$ -apomorphine plus 200 nM domperidone to prevent labelling of class I sites. In both cases it was checked that 'nonspecific' binding (binding in the presence of 200 nM domperidone and of 1  $\mu\text{M}$  DA for class I and II sites, respectively) was not significantly inhibited by the various drugs at their  $\text{IC}_{50}$ .  $^3\text{H}$ -Apomorphine binding to both classes of site was stereospecific and exhibited distinct pharmacological specificity, as shown by the relative affinities of several DA agonists and antagonists, which contrasted with the lack of potency of a variety of non-dopaminergic agents (Table 2). The low potency

of benztropine, an inhibitor of DA uptake, rules out the possibility that class II sites might be linked to this transport system.

Hence the two classes of site have clearly different localizations and pharmacological specificities. Class I sites consist of postsynaptic DA receptors, present on intrastriatal neurones. The increase in their number after ablation of DA neurones probably reflects denervation hypersensitivity<sup>8,20,21</sup>. They are characterized by the high affinity of DA and both DA agonists and DA antagonists ( $K_i$  in nanomolar range), and thus resemble the  $^3\text{H}$ -apomorphine binding sites described by others<sup>13</sup>. Their capacity is about one-third that of DA receptors labelled with  $^3\text{H}$ -butyrophenones<sup>22–24</sup> or  $^3\text{H}$ -domperidone<sup>16</sup>. However, class I sites correspond to a subpopulation of sites constituting ~30% of the total<sup>25</sup> that have a much higher affinity for DA ( $K_i = 7$  nM) than most of the  $^3\text{H}$ -domperidone binding sites ( $K_i = 2$   $\mu\text{M}$ )<sup>26</sup>. Class I sites cannot be  $D_1$  receptors, that is DA receptors linked to adenylate cyclase<sup>1</sup>, because the affinities of domperidone and sulpiride for these sites ( $K_i$  0.5 nM and 100 nM, respectively) are several orders of magnitude higher than for the DA-sensitive cyclase of rat striatum ( $K_i > 10$   $\mu\text{M}$  in both cases)<sup>16,17,27</sup>. They may be postsynaptic DA receptors mediating certain behavioural effects of low doses of DA agonists which are prevented by neuroleptics in moderate dosage and which have often been ascribed to the stimulation of autoreceptors<sup>28,29</sup>. In accordance with the nomenclature of Keabian and Calne<sup>1</sup> we suggest calling these sites  $D_2$  receptors.

On the other hand, class II sites correspond, at least in part, to DA autoreceptors, as shown by the effects of the two neurotoxins 6-OHDA and kainate (Table 1). However, the partial decrease of class II sites, in contrast to the nearly complete loss of tyrosine hydroxylase activity after 6-OHDA, does not

exclude the possibility that ~50% of these sites may be localized on cells other than DA neurones. Autoreceptors, like class I sites, but unlike the major fraction of post-synaptic receptors labelled by  $^3\text{H}$ -butyrophenones and  $^3\text{H}$ -domperidone, are characterized by their high affinity ( $K_i$  in nanomolar range) for most DA agonists. This agrees with electrophysiological, behavioural, and biochemical observations suggesting that autoreceptors are stimulated by DA agonists at low dosage<sup>2,4,28,29</sup>. An interesting exception is bromocriptine, which is approximately 60 times less potent on autoreceptors than on postsynaptic receptors labelled either with  $^3\text{H}$ -apomorphine (class I sites) or  $^3\text{H}$ -butyrophenones<sup>23</sup>. Antipsychotic agents belonging to various chemical groups are recognized by autoreceptors but note that their potency is always lower than on postsynaptic receptors, that is class I sites (Table 2) or  $^3\text{H}$ -butyrophenones and  $^3\text{H}$ -domperidone binding sites<sup>16,23-24</sup>. The number of class II sites found here is approximately five times higher than reported earlier<sup>6</sup> but only slightly higher than that of the  $^3\text{H}$ -apomorphine sites recently described by Titeler *et al.* under the name of  $D_3$  receptors. These  $D_3$  receptors display a drug specificity similar to that of class II sites but were not localized by lesion studies<sup>12</sup>. Thus, class II sites could be termed  $D_3$  receptors.

The discrepancies between various studies concerning drug specificity and localization of sites labelled by  $^3\text{H}$ -apomorphine might be attributable to their heterogeneity with preferential labelling of either class I or class II sites in a given laboratory according to small differences in experimental conditions.

Finally, note that the differential drug specificity of autoreceptors might have therapeutic implications. Because 'on-off' reactions in the treatment of Parkinson's disease (paradoxically inhibitory effects produced by DA agonists when their plasma levels are low) are attributed to selective stimulation of autoreceptors, the low frequency of such reactions in patients treated with bromocriptine<sup>30</sup> might be explained by the low potency of this compound on autoreceptors. In addition, it is unlikely that the antipsychotic activity of antagonists is related to the block-

**Table 2** Inhibition by various agents of the  $^3\text{H}$ -apomorphine binding on the two classes of striatal sites

| Agent                   | $K_i$ values (nM) |          | $(K_i)_{II}/(K_i)_I$ |
|-------------------------|-------------------|----------|----------------------|
|                         | Class I           | Class II |                      |
| <b>DA antagonists</b>   |                   |          |                      |
| Spiperone               | 0.20              | 522      | 2,610                |
| Domperidone             | 0.52              | 3,150    | 6,050                |
| (+)-Butaclamol          | 1.7               | 13.5     | 8                    |
| $\alpha$ -Flupentixol   | 6.8               | 167      | 25                   |
| Haloperidol             | 7.2               | 332      | 46                   |
| Sulpiride               | 97.3              | 100,600  | 1,030                |
| (-)-Butaclamol          | 1,121             | 1,090    | 1                    |
| <b>DA agonists</b>      |                   |          |                      |
| N-Propyl-norapomorphine | 0.40              | 3.5      | 9                    |
| Apomorphine             | 0.65              | 2.9      | 4                    |
| ADTN                    | 1.1               | 4.5      | 4                    |
| Bromocriptine           | 7.2               | 420      | 58                   |
| Dopamine                | 9.9               | 6.1      | 0.6                  |
| <b>Miscellaneous</b>    |                   |          |                      |
| Noradrenaline           | -                 | 65       | -                    |
| Phentolamine            | -                 | 6,100    | -                    |
| Clonidine               | -                 | >30,000  | -                    |
| Serotonin               | -                 | 5,780    | -                    |
| Morphine                | -                 | >150,000 | -                    |
| Benzotripine            | -                 | 4,900    | -                    |

Binding on sites of class I was measured in the presence of 0.8 nM  $^3\text{H}$ -apomorphine and defined as the excess over blank values obtained in the presence of 200 nM domperidone. Values in a typical experiment were: 650 c.p.m. (total binding), 350 c.p.m. (in the presence of 200 nM domperidone) and 250 c.p.m. (in the presence of 1  $\mu\text{M}$  dopamine). Binding on sites of class II was measured in the presence of 6 nM  $^3\text{H}$ -apomorphine and 200 nM domperidone and defined as the excess over blank values obtained in the presence of 1  $\mu\text{M}$  dopamine (see Fig. 1b legend). The effect of each agent was determined at 4-6 concentrations (triplicate determinations) and  $\text{IC}_{50}$  calculated by log-probit analysis of pooled data from 2-4 separate experiments.  $K_i$  values were derived from  $\text{IC}_{50}$  according to the relationship  $K_i = \text{IC}_{50}/(1 + S/K_d)$ .  $(K_d)_I = 0.92$  nM and  $(K_d)_{II} = 2.64$  nM.

ade of autoreceptors as indicated, for instance, by the extremely low potency of sulpiride and by the low potency of spiperone. Furthermore, autoreceptors are probably not blocked during clinical treatment with most antipsychotics at a moderate dosage. In the treatment of psychotics it would therefore seem rational to combine DA agonists with high potency for autoreceptors, and DA antagonists with high relative affinity for postsynaptic receptors. Note that such an apparently paradoxical combination of apomorphine and antipsychotics was recently reported to improve psychotic symptoms significantly, whereas bromocriptine did not show the same activity as apomorphine<sup>31</sup>.

**Table 1** Effect of various lesions on the capacity of the two classes of  $^3\text{H}$ -apomorphine binding site in rat striatum

| Type of lesion                              |               | $^3\text{H}$ -Apomorphine binding (fmol per mg protein) |              |              |
|---|---------------|---|--------------|--------------|
|   |               | Total specific  | Class I      | Class II     |
| Kainate into the striatum (7)               | Contralateral | 203 $\pm$ 15  | 120 $\pm$ 10 | 83 $\pm$ 14  |
|   | Ipsilateral   | 133 $\pm$ 14  | 50 $\pm$ 11  | 83 $\pm$ 10  |
|   | Difference    | -33 $\pm$ 8%  | -57 $\pm$ 9% | +3 $\pm$ 13% |
| 6-OHDA into the medial forebrain bundle (5) | Control       | 249 $\pm$ 31  | 120 $\pm$ 16 | 129 $\pm$ 12 |
|   | Lesioned      | 219 $\pm$ 28  | 155 $\pm$ 24 | 64 $\pm$ 12  |
|   | Difference    | -12%  | +28%         | -50%         |
| 6-OHDA into the substantia nigra (14)       | Contralateral | 235 $\pm$ 7   | 126 $\pm$ 8  | 109 $\pm$ 5  |
|   | Ipsilateral   | 220 $\pm$ 10  | 153 $\pm$ 9  | 68 $\pm$ 8   |
|   | Difference    | -5 $\pm$ 4%   | +24 $\pm$ 7% | -37 $\pm$ 8% |

Lesions were performed in chloral-anaesthetized rats positioned in a David Kopf stereotaxic apparatus. Kainic acid (2.5  $\mu\text{g}$  in 1  $\mu\text{l}$  of solution titrated at pH 7.4) was unilaterally injected (2.5 min infusion) into the striatum at coordinates<sup>32</sup> A = 7.5 mm, L = 2.8 mm and H = 5.1 mm and animals were killed 10-15 days later. Striatal glutamate decarboxylase<sup>33</sup> was decreased by 57  $\pm$  5% in the lesioned compared to contralateral sides (94.2  $\pm$  2.2 nmol per h per mg protein of  $^{14}\text{CO}_2$  formed). In contrast, DOPA decarboxylase activity<sup>33</sup> was not significantly affected (46.2  $\pm$  0.9 compared to 46.3  $\pm$  2.1 nmol per h per mg protein of  $^{14}\text{CO}_2$  formed). 6-OHDA (8  $\mu\text{g}$  in 4  $\mu\text{l}$  of saline containing 0.1% Na ascorbate) was bilaterally injected (5-min infusion) into the medial forebrain bundle at coordinates<sup>34</sup> A = 3.2 mm, L = 1.4 mm, H = -3.0 mm and animals were killed 6-9 days later. Striatal tyrosine hydroxylase activity<sup>37</sup> was significantly decreased by 79% (0.64  $\pm$  0.19 compared to 3.09  $\pm$  0.21 nmol per h per mg protein of  $^3\text{H}_2\text{O}$  formed). In the third group of animals, 6-OHDA (8  $\mu\text{g}$ ) was unilaterally injected into the substantia nigra as described<sup>38</sup> and animals killed 4-5 weeks later. Striatal tyrosine hydroxylase activity was decreased by 89  $\pm$  3% in the lesioned compared to contralateral sides. Binding was measured in the presence of 6 nM  $^3\text{H}$ -apomorphine in the conditions described in Fig. 1b legend. Triplicate determinations on tissues from single animals, the number of which is indicated in parentheses. Binding on the contralateral side of animals lesioned unilaterally with either kainate or 6-OHDA did not significantly differ from that on unlesioned animals (not shown).

## The enkephalinase inhibitor thiorphan shows antinociceptive activity in mice

There is both theoretical and therapeutic interest in establishing whether the signals conveyed by the enkephalins are turned off under the action of a specific peptidase which might, in this case, represent a target for a new class of psychoactive agents. Enkephalinase, a dipeptidyl carboxypeptidase cleaving the Gly<sup>3</sup>-Phe<sup>4</sup> bond of enkephalins<sup>1,2</sup> and distinct from angiotensin converting enzyme (ACE)<sup>3–6</sup>, might be selectively involved in enkephalineric transmission. It is a membrane-bound enzyme<sup>1,7,8</sup> whose localization in the vicinity of opiate receptors in the central nervous system is suggested by parallel regional<sup>1,7,9</sup> and subcellular<sup>10</sup> distributions as well as by the effects of lesions<sup>9</sup>. Such a role is further supported by the ontogenetic development of enkephalinase<sup>11,12</sup>, its substrate specificity accounting for the increased biological activity of several enkephalin analogues<sup>13</sup> and its adaptive increase following chronic treatment with morphine<sup>1,14</sup>. To investigate the functional role of this enzyme further, we have designed a potent and specific enkephalinase inhibitor. We report here that this compound, thiorphan [(DL-3-mercapto-2-benzylpropanoyl)-glycine; patent no. 8008601] protects the enkephalins from the action of enkephalinase *in vitro* in nanomolar concentration and *in vivo* after either intracerebroventricular or systemic administration. In addition, thiorphan itself displays antinociceptive activity which is blocked by naloxone, an antagonist of opiate receptors.

Thiorphan was designed to interact with critical residues of the active site of enkephalinase, as postulated on a hypothetical model (Fig. 1). The model was developed on the assumption that binding of enkephalins to this active site occurs in a manner analogous to that established at the molecular level for carboxypeptidase A (ref. 15). In thiorphan, most of the putative interactions of enkephalins are retained and the binding with the zinc atom at the catalytic site is strongly increased by the introduction of a thiol group in the proper position<sup>16,17</sup>.

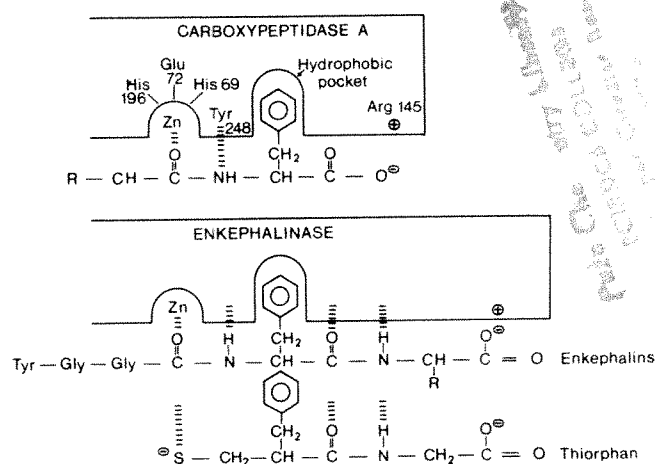

Evidence for the validity of the hypothetical model of the enkephalinase active site was suggested by the high inhibitory potency of thiorphan (Fig. 2). The inhibition of enkephalinase activity from striatal membranes is of a competitive type and the mean  $K_i$  value obtained in various experiments similar to those described in Fig. 2 was  $4.7 \pm 1.2$  nM.

Furthermore, thiorphan displays a good selectivity towards enkephalinase among the various enkephalin-hydrolysing

activities already described in brain tissues. Regarding ACE activity in mouse striatum<sup>18</sup> which is also able to cleave the Gly<sup>3</sup>-Phe<sup>4</sup> peptide bond of enkephalins<sup>19</sup>, the  $K_i$  of thiorphan was  $150 \pm 30$  nM (not shown) which corresponds to a 30-fold lower potency than towards enkephalinase. It is interesting that captopril (SQ 14,225), an inhibitor of ACE, displays an inverse specificity pattern, being much more potent on this enzyme ( $K_i = 7$  nM) than on enkephalinase ( $K_i = 10$   $\mu$ M)<sup>4,16</sup>. These observations further demonstrate that enkephalinase and ACE, in spite of their analogies<sup>3</sup>, are different enzymes<sup>4,14</sup>. In addition, the formation of either <sup>3</sup>H-Tyr or <sup>3</sup>H-Tyr-Gly, as detected by TLC, following incubation of striatal membranes in the presence of 20 nM <sup>3</sup>H-Leu<sup>5</sup>-enkephalin and in the absence of puromycin (which inhibits the formation of both compounds) was not affected by thiorphan in concentrations as high as 10  $\mu$ M. This indicates that thiorphan does not significantly inhibit the aminopeptidase<sup>20–26</sup> or the putative endopeptidase<sup>6</sup> activities responsible for *in vitro* cleavage of the enkephalin molecules at peptide bonds other than Gly<sup>3</sup>-Phe<sup>4</sup>.

The ability of thiorphan to inhibit enkephalinase activity *in vivo* was evaluated by determining the effect of the drug on the analgesia elicited by (D-Ala<sup>2</sup>-Met<sup>5</sup>)-enkephalin administered intracerebroventricularly (i.c.v.) in low dosage. The D-Ala<sup>2</sup> substitution in this compound preserves opiate receptor affinity and bestows resistance to aminopeptidases<sup>27</sup>, but does not markedly impair recognition by enkephalinase as long as the carboxyl of Met<sup>5</sup> is not amidified<sup>13</sup>.

A short-lasting, nonsignificant analgesia was recorded on the tail-withdrawal test<sup>28</sup> when (D-Ala<sup>2</sup>-Met<sup>5</sup>)-enkephalin was administered (20  $\mu$ g, i.c.v.) alone (Fig. 3 and Table 1). Co-administration of thiorphan, either i.c.v. or systemically, resulted in a strong potentiation of the analgesic effect of the opioid pentapeptide which was nearly maximal in all animals over ~90 min and still significant ~2 h after intravenous (i.v.) administration and 4 h after i.c.v. administration. In contrast, the effect elicited by (D-Ala<sup>2</sup>-Met<sup>5</sup>)-enkephalinamide, an analogue poorly recognized by enkephalinase<sup>13</sup>, was not significantly modified by thiorphan. Interestingly, neither thiorphan alone (30  $\mu$ g or 60  $\mu$ g, i.c.v.) nor the opiate receptor antagonist naloxone (1 mg per kg, subcutaneously (s.c.))

**Fig. 1** Hypothetical model of the active site of enkephalinase and of the binding of enkephalins and thiorphan. The model was developed by analogy with the active site of carboxypeptidase A (upper part) as proposed by Quiocho and Lipscomb<sup>15</sup>. Enkephalinase is likely to contain a zinc atom<sup>3</sup> that, as in carboxypeptidase A, would bind the carbonyl group of the peptide bond to be cleaved. Evidence for the presence of a 'dead-end hydrophobic pocket' analogous to that of carboxypeptidase A<sup>15</sup> but which seems absent in ACE<sup>16</sup> is given by the recognition of di- and tripeptides only when containing an aromatic amino acid<sup>37</sup>. Interaction of the two C-terminal peptide bonds of enkephalins with the active site is suggested by the diminished recognition of analogues in which they are modified<sup>37</sup>. The free carboxyl would interact with a positively charged residue (corresponding to Arg 145 in carboxypeptidase A) as shown by the diminished recognition of enkephalin analogues in which it is replaced by an alcohol group, amidified, esterified or localized in a proline ring<sup>13,14</sup>.

**Fig. 2** Inhibition of enkephalinase activity from mouse striatum by thiorphan. A washed particulate fraction from mouse striatum was prepared according to Malfroy *et al.*<sup>1</sup>. Protein concentration in the assay mixture was 40 µg per 100 µl but similar results were obtained for concentrations varying over 1–200 µg per 100 µl. After a 15-min preincubation at 25 °C, incubations were started by addition of a mixture containing 20 nM (<sup>3</sup>H-Leu<sup>5</sup>)-enkephalin previously purified by Porapak column chromatography<sup>24</sup>, 0.1 mM puromycin, an aminopeptidase inhibitor<sup>25</sup>, 1 µM captopril, an ACE inhibitor<sup>16</sup>, 0.1 mM 2-mercaptoethanol and unlabelled (Leu<sup>5</sup>)-enkephalin in the indicated concentrations (all final concentrations in 50 mM Tris-HCl buffer, pH 7.4). Incubations (15 min at 25 °C) were stopped by addition of HCl (0.07 M, final molarity). Blanks were obtained by adding HCl before the beginning of incubation and represented ~20% of the uninhibited enzyme activity. <sup>3</sup>H-Labelled metabolites plus unlabelled carriers were separated by TLC on silica gel plastic sheets (Merck, Darmstadt) using the following system: BuOH, AcOH, AcOEt, H<sub>2</sub>O (1:1:2:1). Spots, localized after a ninhydrin spray, had the following *R<sub>f</sub>* values: Tyr 0.55, Tyr-Gly 0.47, Tyr-Gly-Gly 0.39, (Leu<sup>5</sup>)-enkephalin 0.81. The Tyr-Gly-Gly spots were cut out and their radioactivity estimated by liquid scintillation counting. Left: Effect of thiorphan in increasing concentrations on the hydrolysis of (<sup>3</sup>H-Leu<sup>5</sup>)-enkephalin (20 nM) by mouse striatal enkephalinase. Means ± s.e.m. of triplicate determinations in the same experiment. This experiment was repeated 12 times leading to an IC<sub>50</sub> value of 4.7 ± 1.2 nM. Right: Dixon plots of enkephalinase inhibition by thiorphan. Each point represents the mean of duplicate determinations. *K<sub>i</sub>* value obtained in this experiment was 3 nM and was confirmed in another similar experiment.

**Table 1** Activity of thiorphan on responses to nociceptive stimuli in mice

| Tests                   | Treatments   | Latency (s)    | P       |
|-------------------------|--|----------------|---------|
| Tail withdrawal (48 °C) | Controls   | 3.1 ± 0.4 (15) |         |
|                         | Thiorphan (30 µg, i.c.v.)  | 4.2 ± 1.1 (6)  |         |
|                         | Thiorphan (60 µg, i.c.v.)  | 2.7 ± 0.4 (9)  |         |
|                         | Naloxone (1 mg per kg, i.v.)   | 3.2 ± 0.3 (9)  |         |
|                         | (D-Ala <sup>2</sup> -Met <sup>5</sup> )-enkephalin (20 µg, i.c.v.)                                   | 3.4 ± 0.2 (14) |         |
|                         | (D-Ala <sup>2</sup> -Met <sup>5</sup> )-enkephalin (20 µg, i.c.v.) + thiorphan (30 µg, i.c.v.)       | 9.6 ± 0.9 (14) | <0.001  |
|                         | (D-Ala <sup>2</sup> -Met <sup>5</sup> )-enkephalin (20 µg, i.c.v.) + thiorphan (100 mg per kg, i.v.) | 7.6 ± 0.8 (14) | <0.001  |
|                         | (D-Ala <sup>2</sup> -Met <sup>5</sup> )-enkephalinamide (2.5 µg, i.c.v.)                             | 3.2 ± 0.4 (6)  |         |
|                         | (D-Ala <sup>2</sup> -Met <sup>5</sup> )-enkephalinamide (2.5 µg, i.c.v.) + thiorphan (30 µg, i.c.v.) | 3.3 ± 0.6 (6)  |         |
|                         | (D-Ala <sup>2</sup> -Met <sup>5</sup> )-enkephalinamide (15 µg, i.c.v.)                              | 12.5 ± 1.1 (6) | <0.001  |
|                         | (D-Ala <sup>2</sup> -Met <sup>5</sup> )-enkephalinamide (15 µg, i.c.v.) + thiorphan (30 µg, i.c.v.)  | 13.8 ± 1.2 (6) | <0.001* |

|                         | Controls (solvent, i.v.)   | 63 ± 11 (20)   |         |
|                         | Thiorphan (100 mg per kg, i.v.)  | 129 ± 22 (10)  | <0.02   |
|                         | Thiorphan (100 mg per kg, i.v.) + naloxone (1 mg per kg, s.c.)                                       | 68 ± 16 (10)   | <0.05†  |
| Hotplate jump (50 °C)   | Naloxone (1 mg per kg, s.c.)   | 43 ± 8 (10)    | <0.05   |
|                         | Controls   | 186 ± 11 (20)  |         |
|                         | Thiorphan (60 µg, i.c.v.)  | 245 ± 14 (20)  | <0.05   |
|                         | Thiorphan (60 µg, i.c.v.)  | 129 ± 13 (20)  | <0.05   |
|                         | + naloxone (1 mg per kg, s.c.)   | 129 ± 13 (20)  | <0.001† |

The tail withdrawal test was performed as described in Fig. 3 legend. The latency values obtained for each animal during the 240-min experimental period (13 determinations) were averaged. The hotplate test<sup>24,26</sup> was carried out at either 55 °C or 50 °C and the jump latency recorded 15 min after drug administration, without 'cutoff time'. Naloxone was administered at the same time as thiorphan. Results are the means ± s.e.m. of the number of experiments indicated in parentheses.

\* Non-significant compared with (D-Ala<sup>2</sup>-Met<sup>5</sup>)-enkephalin alone.

† Compared with thiorphan alone.

**Fig. 3** Effects of thiorphan on the analgesic activity of (D-Ala<sup>2</sup>-Met<sup>5</sup>)-enkephalin in the mouse tail withdrawal test. Swiss mice (20–22 g, Charles River) were tested at 20-min intervals over 4 h. The time (in seconds) between tail immersion into a water bath maintained at 48 °C and withdrawal was recorded as the response latency<sup>26</sup>. The 'cutoff time' was 15 s and the value at zero time represents the average of three determinations carried out before drug injection. (D-Ala<sup>2</sup>-Met<sup>5</sup>)-enkephalin (20 µg) was administered i.c.v. under a volume of 5 µl (3% ethanolic solution) either alone or together with thiorphan (30 µg). In the third group of animals thiorphan was administered i.v. (100 mg per kg) 15 min before (D-Ala<sup>2</sup>-Met<sup>5</sup>)-enkephalin (20 µg, i.c.v.). Controls received an i.c.v. administration of solvent alone. Each point represents the mean ± s.e.m. of data from 14 or 15 experiments. The shaded area corresponds to means ± s.e.m. of controls. Δ, (D-Ala<sup>2</sup>-Met<sup>5</sup>)-enkephalin + thiorphan (i.c.v.); ○, (D-Ala<sup>2</sup>-Met<sup>5</sup>)-enkephalin + thiorphan (i.v.); □, (D-Ala<sup>2</sup>-Met<sup>5</sup>)-enkephalin alone. \* *P* < 0.05; \*\* *P* < 0.01; \*\*\* *P* < 0.001.

modified the responsiveness of mice in the tail-withdrawal test, at any time after administration (Table 1).

Because the involvement of endogenous opioid peptides in the response to various nociceptive stimuli, as revealed by the hyperalgesic effect of naloxone, seems to vary according to the type of nociceptive stimulus used<sup>29-33</sup>, we have determined the effect of thiorphan in the hotplate jump test<sup>34,35</sup>. On this test, performed at either 55 °C or 50 °C, thiorphan administered either i.c.v. or i.v. displayed a clear antinociceptive activity which was probably mediated by opiate receptors as it was completely prevented by administration of naloxone in moderate dosage (Table 1). This opiate antagonist, when administered alone, significantly decreased the latency of the jump response as previously shown<sup>29,32</sup>.

The effect of thiorphan cannot be mediated by inhibition of aminopeptidase and is unlikely to involve ACE inhibition because its antinociceptive activity was observed at dosages approximately 30 times lower than those required for captopril<sup>36</sup>, whereas the latter compound is approximately 20 times more potent than thiorphan as an ACE inhibitor. Hence, the present observations strongly support the hypothesis that enkephalinase is selectively responsible for the metabolism of endogenous enkephalins. The reasons for which thiorphan elicits analgesia (and naloxone hyperalgesia) in one test but not in others are unclear but might be that different noxious stimuli elicit release of endogenous opioid peptides to a variable extent. Thus, thiorphan might constitute a useful tool for investigating the involvement of enkephalins in a variety of behavioural situations and might also represent the prototype of a new class of pharmacological agent.

## Herpes simplex virus DNA sequences in the CNS of latently infected mice

Carlos V. Cabrera\*, Charles Wohlenberg, Harry Openshaw†, Manuel Rey-Mendez‡, Alvaro Puga & Abner Louis Notkins

Laboratory of Oral Medicine, National Institute of Dental Research, National Institutes of Health, Bethesda, Maryland 20205

It has been amply documented that herpes simplex virus (HSV) persists in sensory ganglia of the peripheral nervous system (PNS)<sup>1-4</sup>. In contrast, HSV latency in the central nervous system (CNS) has not been well characterized. Corneal inoculation of virus results in a productive viral infection in the CNS during the first week after inoculation<sup>5</sup>, indicating that the virus can progress from the PNS to the CNS. During latency, HSV has been found by co-cultivation of CNS tissue in only a very small fraction of inoculated mice<sup>7,8</sup>. We have used here molecular hybridization techniques to analyse the fate of viruses that reach the CNS by anatomical pathways. We show that 6 days after corneal inoculation of HSV-1 a productive viral infection was present in brain tissue as well as in peripheral ganglia in at least 90% of the inoculated mice. The mortality during this acute phase was only 2%. In the survivors, latent HSV could be recovered by explantation from 95% of the trigeminal ganglia, but only 5% of the brain tissue explants of the same mice yielded infectious virus. However, HSV DNA sequences were detected in the brains of 30% of mice which harboured latent HSV in their trigeminal ganglia. These results suggest that viruses that progress from the PNS into the CNS are not eliminated, but are capable of establishing a latent infection in the CNS that cannot be reactivated by explantation techniques.

Six- to eight-week-old female BALB/cJ mice were inoculated by corneal scarification with approximately  $5 \times 10^6$  plaque-forming units (PFU) of the F strain of type 1 HSV (American Type Culture Collection). The virus was grown in primary rabbit kidney cells and concentrated by ultracentrifugation (stock pool of  $10^6$  PFU ml<sup>-1</sup>). For infectivity assays, homogenates or minced explants of individual organs were monitored for ability to induce cytopathic effects in monolayers of primary rabbit kidney cells<sup>3-5</sup>. For hybridization experiments, DNA was extracted from individual brain stems and hemispheres. Hybridization was to a <sup>32</sup>P-labelled HSV DNA probe prepared by nick translation<sup>9</sup>, purified in alkaline Sephadex G-200 (ref. 10) and free of fold-back DNA<sup>4</sup>. The conditions for the DNA-DNA hybridization reactions were as described previously<sup>4,11,12</sup>.

Table 1 shows that infectious HSV could be detected in homogenates of trigeminal ganglia from all of the mice killed 6 days after corneal inoculation of HSV (acute stage). At this time, infectious HSV was also detected in the brain stems of 18 out of 20 mice, and in the brain hemispheres of 6 out of 20 mice. DNA-DNA hybridization confirmed and extended these findings. Figure 1a shows the hybridization kinetics of a trace of <sup>32</sup>P-HSV DNA with DNA from individual brain stems and hemispheres taken from mice 6 days after inoculation. All 10 DNA preparations increased the rate of reassociation of the tracer over the self-reassociation rate in the presence of uninfected mouse brain DNA. However, the extent of the rate increase was not the same for the different preparations tested. The slopes of the curves show that the brain stems from acutely infected mice contained more viral DNA than the hemispheres from the same mice. The range of viral equivalents per 100 cells was 1-5 for the brain hemispheres and 22-178 for the brain stems (Table 2). In each animal the brain stem had more viral

**Table 1** Infectivity assay of mouse ganglia and brains

| Time after inoculation | Trigeminal ganglia | Brain stem | Brain hemispheres |
|------------------------|--------------------|------------|-------------------|
| <b>6 days</b>          |                    |            |                   |
| Homogenates*           | 20/20              | 18/20      | 6/20              |
| <b>8 weeks</b>         |                    |            |                   |
| Homogenates*           | 0/20               | 0/20       | 0/20              |
| Explant†               | 38/40              | 0/20       | 1/20              |

Results are expressed as the ratio of positive isolates from individual mice to the total number of mice tested.

\* The appropriate tissue was homogenized in glass Ten-Broek tissue grinders. After freezing and thawing to disrupt viable cells, the cell debris was pelleted by low-speed centrifugation and the supernatant fluid was cultured on primary rabbit kidney cells. Cultures were followed for viral-induced cytopathology (CPE) for 5 days.

† Ganglia were explanted on monolayers of primary rabbit kidney cells in Eagle's minimal essential media supplemented with 3% fetal bovine serum (MEM). CPE appeared in the cell monolayer by 8 days in over 95% of the explant cultures that yielded HSV. For CNS explants, the appropriate tissues were minced and placed in MEM without a cell monolayer. The media was changed on alternate days and cultured for HSV. After 6–8 days, the explant tissue was homogenized and assayed for infectious virus\*. As shown previously, this technique can detect *in vitro* reactivation in 100% of latently infected ganglia after only 48 h of culture<sup>5</sup>. In contrast, CPE does not usually appear on the indicator cell monolayer before 5 days in the standard explantation and co-cultivation technique<sup>3</sup>.

sequences than the brain hemispheres, ranging from 8-fold for animal no. 4 to 60-fold for animal no. 3.

Mortality in the inoculated animals was only 2%, despite the productive viral infection in the CNS. Furthermore, 8 weeks after inoculation, trigeminal ganglionic homogenates were negative, but 38 of 40 ganglionic explants yielded infectious HSV by *in vitro* reactivation. Although these conditions essentially define the latent stage of the ganglionic infection, they did not apply to the CNS tissue, as HSV could be recovered by explantation in only 1 of 20 mice (Table 1). This low recovery rate from CNS explants could be explained in two ways: either the virus is eliminated from the CNS during the acute infection or the viral genome is present in the CNS in a form that cannot be readily reactivated by explantation techniques. To investigate these alternatives, a total of 20 mice in three separate inoculation schedules were killed 8 weeks after inoculation with HSV. DNA was extracted from the brain stems and hemispheres and each individual preparation was hybridized to a <sup>32</sup>P-HSV DNA probe.

The highest possible mass ratios of brain DNA to probe were used to maximize the detection level. However, due to the limited amount of DNA available from single organs, the sensitivity level was never higher than 1 viral equivalent per 1,500 cells, and usually it was in the range of 1 viral equivalent per 300–800 cells. Notwithstanding, DNA from 3 out of 20 hemispheres and 4 out of 20 stems increased significantly the reassociation rate of the probe over the control (Fig. 1*b*). An average number of copies per cell was calculated for the seven positive organs using the rates determined experimentally and the known parameters of each hybridization reaction. The three positive hemispheres had 0.4–9 copies per 100 cells; the four positive stems had 0.5–6 copies per 100 cells. Unlike the acute stage, latently infected brain stems and hemispheres had comparable amounts of viral DNA, although the number of sequences in either tissue varied over a 10–20-fold range (Table 2; only positive cases shown). These calculations are based on the assumption that the entire viral genome is present, although the maximum extent of hybridization never exceeded 40% (H-8) and more often was 12–20% (S-9; S-11). This assumption is only valid to determine an average number of copies for the DNA sequences that hybridize. Only one animal (no. 7) contained viral sequences in both brain stem and hemispheres; all other positive animals had viral DNA in either tissue, but not both.

Latent HSV has previously been detected by co-cultivation in 9% of mouse brains following experimentally induced viraemia<sup>7</sup> and in 9% of mouse spinal cords after rear-footpad inoculation<sup>8</sup>. In those reports mortality was high, unlike the present study. However, in our experiments, 5% of the brain hemispheres were shown to contain virus, a number not very different from those reported previously. Clearly, explantation results in a large underestimation of the actual number of animals that harbour viral DNA sequences in the CNS. As shown, a total of 6 out of 20 mice (30%) have HSV DNA in the brain stem and/or hemispheres, a fraction six times higher than that found by explantation. Inoculation of a viral dose sufficiently large to increase the mortality rate may increase the fraction of surviving animals with detectable viral DNA sequences in the CNS.

**Fig. 1** Hybridization kinetics of <sup>32</sup>P-HSV DNA ( $1.2 \times 10^8$  c.p.m. per  $\mu$ g) in the presence of DNA from brain stems (S) or brain hemispheres (H) of HSV-infected mice. Brain tissues were homogenized in 2.2M sodium trichloroacetate (NaTCA), pH 7.4, 10 mM EDTA, followed by phenol-chloroform extraction and ethanol precipitation. NaTCA inhibits DNase activity present in large quantities in nervous tissue. DNA preparations were treated with RNase, proteinase K, re-extracted and sonicated to an average piece size of 7S in alkaline sucrose. DNA yield was  $300 \pm 50 \mu$ g for brain hemispheres and  $40 \pm 15 \mu$ g for brain stems. *a*, 6 days post-inoculation; the reaction mixtures contained 0.8–1.0 ng ml<sup>-1</sup> <sup>32</sup>P tracer and 11–12 mg ml<sup>-1</sup> brain hemisphere DNA or 5–6 mg ml<sup>-1</sup> brain stem DNA. *b*, 8 weeks post-inoculation; the reaction mixtures contained 1 ng ml<sup>-1</sup> <sup>32</sup>P tracer and 15 mg ml<sup>-1</sup> hemisphere DNA or 13–20 mg ml<sup>-1</sup> stem DNA. A control was run in the presence of uninfected mouse brain DNA (UMB). Mixtures were adjusted to 0.48 or 1.0 M phosphate buffer, pH 6.8, and incubated in siliconized glass capillaries at 70–72 °C. The inverse of the fraction of <sup>32</sup>P-DNA remaining as single strands ( $1/f_{\infty}$ ) is plotted as a function of the equivalent  $C_0 t$  ( $E C_0 t$ ), corrected to 0.18 M Na<sup>+</sup> (ref. 12).

The detection level of the hybridization reactions is limited by the scarcity of DNA from single CNS tissues and by the uncertainty as to which areas of the brain are most likely to be positive for viral sequences. The hybridization rates used to calculate the number of viral copies have been obtained from a least-squares regression fit of three experimental points to a straight line, but in many cases a fit to a two-component curve may also be possible (as shown in Fig. 1). A fit to a straight line provides only valid information for comparisons to be drawn between the various tissues. Thus, the results would not warrant the conclusion that all of the viral genome is present in the CNS during the latent stage. In fact, the sequences detected may correspond to an unbalanced representation of portions of the genome, such as is found in defective particles. The presence of defective particles may explain the absence of significant reactivation by explantation.

HSV reaches sensory ganglia in the PNS by intra-axonal retrograde transport<sup>13-15</sup>. The same anatomical pathway is the most likely route for virus to reach the CNS, as the bipolar axon of trigeminal neurones continues past the ganglion and synapses into the brain stem. A productive viral infection in the brain stem and hemispheres can then occur concomitantly with the acute stage of the ganglionic infection, setting the stage for subsequent latency in the CNS.

The finding of latent viral DNA in the brains of experimental animals suggests a possible role for HSV in neurological disorders of unknown aetiology. If the viral genome or portions of it were shown to be present in human brains, in the absence of complete viral reactivation certain genes could be expressed

under the influence of various stimuli. The resulting viral proteins might interfere with nerve cell function by altering cell membranes, setting up abnormal storage material or provoking a local immune response.

We thank Dr Edouard Cantin for helpful discussions, Drs Patrick McClintock and Martin Haspel for criticisms, Mrs Jeannette Murphy and Edith Rian for secretarial help, and Dr D. E. Kohne for communicating methodology before its publication.

Rate increase factors and copies per cell were determined as described<sup>4</sup>, using  $2.46 \pm 0.171 \text{ mol}^{-1} \text{ s}^{-1}$  as the rate constant for the reassociation of nick-translated HSV DNA in the presence of uninfected mouse brain DNA (an average of five experiments). The rate constants of the hybridization reactions were determined from the least-squares fit of the curves in Fig. 1. A total of 20 brain stems and their corresponding hemispheres were tested at 8 weeks post-inoculation; only organs that gave rate increase  $\geq 2$  were considered positive and are reported here. The mass ratios of brain DNA to <sup>32</sup>P-HSV DNA ranged from  $5 \times 10^6 : 1$  to  $1 \times 10^8 : 1$ . Results are indicated  $\pm$ s.e. R-15 and R-24 are reconstitution experiments containing 15-fold and 24-fold excess of unlabelled HSV DNA over <sup>32</sup>P tracer, respectively; the rate increases in these two reactions agree with those expected from the reconstitution conditions.

It is widely believed that immunoglobulin genes might encode at least part of the receptor for antigen on the T lymphocyte. Evidence supporting this comes from the effects of anti-immunoglobulin idiotype antibodies on cellular immune networks<sup>1-4</sup> and from the presence of idiotypes on immunologically active factors from T cells<sup>5-7</sup>. Detailed molecular characterization of the receptor, however, has been seriously hampered by the lack of a suitable cellular source from which it might be isolated. The recent demonstration by Kemp *et al.*<sup>8,9</sup> that thymocytes and certain cultured lines of mouse T lymphoma cells contain polyadenylated RNA molecules encoded by the immunoglobulin C<sub>μ</sub> gene (C<sub>μ</sub> RNA) prompted us to identify the corresponding protein molecules in those cells. As the haploid mouse genome contains a single C<sub>μ</sub> gene<sup>10</sup>, any polypeptide encoded by this gene should react with at least some of the antibodies present in rabbit anti-mouse IgM antiserum. In this letter we report that a number of T lymphoma lines, regardless of whether they contain C<sub>μ</sub> RNA, synthesize no detectable  $\mu$  polypeptides.

The cloned T lymphoma lines chosen for study were STRij-4-2.2 (ST4), STRij-1.3 (ST1), WEHI-22.1 (W22), EL-4.1 (EL4) (described in ref. 8) and WEHI-112.1 (W112): they contained 33, <1.5, 3, <1.5 and 30–50 molecules of C<sub>μ</sub> RNA per cell, respectively. In addition, two B lymphoma cell lines, WEHI-231 (W231) ( $\mu$ ,  $\kappa$ ) and WEHI-279 (W279) ( $\mu$ ,  $\kappa$ ), a mastocytoma line P815 (respectively, 95, 195 and <0.3 C<sub>μ</sub> RNA molecules per cell<sup>8</sup>) and an Abelson pre-B lymphoma cell line 18–81 (ref. 11) were used as positive or negative controls in the search for  $\mu$  polypeptide chains.

The presence of C<sub>μ</sub> RNA molecules in ST4 and W112 was repeatedly confirmed during experiments described here, indicating that C<sub>μ</sub> gene transcription occurs continuously in these cell lines.

A 'sandwich' radioimmunoassay (RIA) technique using <sup>125</sup>I-labelled antibodies was used to test cell extracts for  $\mu$  polypeptide content and Fig. 1a shows the results of an experiment in which extracts of W231, P815 and ST4 were examined. No binding whatever was apparent with ST4 or P815, whereas in

**Fig. 1** Detection of  $\mu$  polypeptides in detergent lysates of lymphoma cells. Cells ( $10^6 \text{ ml}^{-1}$ ) were solubilized in Triton X-100 buffer (0.01 M Tris-HCl, 0.15 M NaCl, 0.5% Triton X-100, pH 7.5) containing 1% (w/v) bovine serum albumin (BSA), by incubation at  $0^\circ\text{C}$  for 20 min. Nuclei were removed by centrifugation at 10,000 r.p.m. for 30 min. Supernatants were tested by solid-phase RIA<sup>16</sup>. Anti- $\mu$  antiserum, obtained from rabbits immunized with purified myeloma HPC-76 IgM ( $\mu, \kappa$ ), was affinity-purified on myeloma MOPC 104E IgM ( $\mu, \lambda$ )-Sepharose adsorbent. Microtitre plates were coated with purified anti- $\mu$  Ig ( $20 \mu\text{g ml}^{-1}$ ) and then incubated with dilutions of cell extracts or of purified 104E IgM. After washing, anti- $\mu$   $^{125}\text{I}$ -Ig was added ( $10 \mu\text{Ci } \mu\text{g}^{-1}$ , 20,000 c.p.m. per well), and incubation carried out overnight. Plates were washed and individual wells counted in a Packard  $\gamma$  counter. *a*, Titration curves for extracts of W231, P815 and ST4; *b*, binding data for detergent extracts of various cell lines, each tested at a concentration of  $10^6 \text{ cells ml}^{-1}$  compared to MOPC 104E at  $10 \mu\text{g ml}^{-1}$ .

W231, activity (IgM) could be detected even after a 10,000-fold dilution. Using purified myeloma MOPC 104E IgM as a reference standard, the amount of IgM in W231 was estimated at  $3 \times 10^5$  molecules per cell. Thus the number of  $\mu$  molecules in P815 or ST4 cannot exceed 30 per cell. Other  $C_\mu$  RNA-containing T lymphoma lines (W112 and W22) were tested by sandwich RIA and again no  $\mu$  polypeptides were detected (Fig. 1*b*).

We considered the following possibilities to account for our failure to detect  $\mu$  polypeptides in cells producing  $C_\mu$  RNA: (1) The anti- $\mu$  antibodies bind only to carbohydrate determinants present on IgM but not on T lymphoma cell  $\mu$  polypeptides.

(2) A specific protease in T lymphoma cells degrades  $\mu$  polypeptides.

(3) The anti- $\mu$  antibodies cannot bind  $\mu$  chains that are not associated with light chains.

(4)  $\mu$  polypeptides in T lymphoma cells are associated with other proteins which render antigens, which would otherwise bind anti- $\mu$  antibodies, inaccessible.

(5) A fragment of  $\mu$  chain containing only one or a few antigenic sites is synthesized by T lymphoma cells.

Possibility (1) was eliminated by demonstrating that oxidation of HPC-76 myeloma IgM with  $\text{NaIO}_4$ , in conditions known to degrade serologically detectable carbohydrate<sup>12</sup>, did not affect

its reactivity towards anti- $\mu$  antibodies as determined by RIA.

Possibility (2) was ruled out by an experiment in which equal numbers of ST4 and W231 cells were mixed before lysis and the mixed extract titrated for IgM activity after overnight incubation at room temperature. No reduction in IgM titre compared to an extract of W231 alone was found. To test the further possibility that cellular proteases could act on T-cell  $\mu$  polypeptides but not on IgM, we pulse-labelled cells with  $^{35}\text{S}$ -methionine and searched for labelled proteins after immunoprecipitation of cell extracts with anti- $\mu$  antibodies (Fig. 2). Only with the two B lymphoma lines, W231 and W279, was specifically precipitated labelled protein apparent. As little as 1% of the material present in W231 would have been detected as a specific band, but none was found in the T lymphoma cell lysates. As W231 cells contain on average  $3 \times 10^5$  IgM molecules per cell and have a doubling time in culture of 12–14 h, they must synthesize at least 6,000 molecules per cell during a 15-min labelling period. ST4 cells contain 33  $C_\mu$  RNA molecules per cell compared with 95 in W231 and would be expected to synthesize 2,000 molecules in the same time period. Thus, if fewer than 60 out of 2,000 newly synthesized  $\mu$  molecules remain in ST4 cells after 15 min, their half life would have to be less than 1 min, a considerably shorter time than that required for complete translation of a  $\mu$  polypeptide chain.

Possibility (3), that anti- $\mu$  antibodies bind only to antigens formed by H chain-L chain association was ruled out by demonstrating that  $\mu$  polypeptides, even after SDS-gel electrophoresis, could specifically bind the antibodies. Figure 3 shows the results of a filter affinity transfer experiment<sup>13,14</sup> in which purified IgM (MOPC 104E) was electrophoresed in SDS and transferred to chemically activated paper to which anti- $\mu$  antibodies had been attached. Subsequent incubation with anti- $\mu$   $^{125}\text{I}$ -antibodies revealed the presence of a radioactive protein zone corresponding in size to  $\mu$  chain in the purified IgM channel. Thus, at least a fraction of the antibody molecules can recognize  $\mu$  chains not associated with L chains.

This conclusion was confirmed in RIA of extracts of an Abelson lymphoma cell line, 18-81, which synthesizes  $\mu$  chains but no L chains<sup>11</sup>. In these experiments (not shown), neither the shape of the titration curve nor the maximum counts per min bound with 18-81 was different from the corresponding parameters for W231, implying that L chains contributed few, if any, antigens reactive with the present antiserum.

Possibility (4) was tested by performing RIA on extracts of W231 and ST4 cells which had been subjected to SDS treatment before assay so as to dissociate protein-protein interactions. Although SDS treatment severely reduced the ability of W231  $\mu$  chain to fix anti- $\mu$  antibodies, residual antigenic activity was nonetheless clearly present in W231 but not in ST4.

Should T lymphoma cells synthesize only a fragment of normal  $\mu$  chain, RIA techniques may severely underestimate or even fail to detect it, depending on the number of antigenic sites contained. In the immunoprecipitation experiments of Fig. 2, anti- $\mu$  antibodies were used in large ( $> 10$ -fold) excess over the amount of IgM known to be present in the W231 extract, to facilitate antibody interactions with weak antigens. However, only in the two B lymphoma cell lines were  $\mu$  polypeptides detected: in the T lymphoma lines, neither intact  $\mu$  polypeptides nor polypeptides of altered size were detected. A single  $\mu$  antigenic determinant per molecule would have resulted in specific precipitation in this test.

At face value, the data herein do not support the inference, from the existence of  $C_\mu$  RNA in T lymphoma and thymus cells, that the  $C_\mu$  gene may specify part of the T-cell antigen receptor<sup>8,9</sup>. If  $C_\mu$  RNA concentration was the sole determinant of  $\mu$  polypeptide production, ST4 cells should contain about  $10^5$   $\mu$  molecules per cell, which would have been readily detected. Furthermore, the  $C_\mu$  RNA molecules in ST4 cells contain nucleotide sequences corresponding to all four  $C_\mu$  domains<sup>15</sup> and, if translated, their protein products would be expected to express the antigenic determinants required for serological detection. Therefore, neither the qualitative characteristics (as

**Fig. 2** Immunoprecipitation of detergent extracts of biosynthetically labelled lymphoma cells.  $2 \times 10^7$  cells were labelled for 15 min at  $37^\circ\text{C}$  in 10 ml culture medium containing 10% fetal calf serum and  $50 \mu\text{Ci ml}^{-1}$   $^{35}\text{S}$ -methionine (specific activity  $\sim 1,000 \text{ Ci mmol}^{-1}$ ). Incubations were terminated by the addition of 1 ml  $10\times$  concentrated Triton X-100 buffer and supernatants were prepared as in Fig. 1 legend. Samples of each supernatant containing equal amounts of radioactivity were reacted with  $10 \mu\text{g}$  anti- $\mu$  ( $\alpha\mu$ ) Ig, or with  $10 \mu\text{g}$  normal rabbit IgG (NR) by overnight incubation at  $4^\circ\text{C}$ .  $10 \mu\text{l}$  of packed, formalin-fixed *Staphylococcus A* organisms were added to each sample, incubated for 1 h at  $4^\circ\text{C}$  and then washed twice in Triton X-100 buffer containing 1% (w/v) BSA, pH 8.5 (HCl), and once in Triton X-100 buffer lacking BSA. Samples were subject to SDS electrophoresis on 12% polyacrylamide gels<sup>17</sup>, stained to visualize molecular weight marker proteins and then fluorographed<sup>18</sup>. H, L, positions of IgM heavy chain and light chain, respectively.

**Fig. 3**  $\mu$  polypeptides do not require associated L chains to react with anti- $\mu$  antibodies. The indicated amounts of purified MOPC 104E IgM and a molecular weight marker mixture of proteins containing phosphorylase *b* (94,000), BSA (68,000) and ovalbumin (48,000) were separated by SDS-gel electrophoresis. The gel was then soaked in phosphate-buffered saline (PBS) containing 1% Triton X-100 to leach out SDS. Proteins were transferred from the gel to a strip of Whatman 540 paper to which anti- $\mu$  Ig had previously been attached. After transfer, the gel was stained with Coomassie blue 250R and the paper was reacted by overnight incubation with  $20 \text{ ml}$  anti- $\mu$ - $^{125}\text{I}$ -Ig ( $2 \times 10^6 \text{ c.p.m. ml}^{-1}$ , specific activity  $10 \mu\text{Ci } \mu\text{g}^{-1}$ ) dissolved in PBS containing 0.05% Tween 20, 1% (w/v) BSA. Filter paper was chemically activated<sup>14</sup> and antibodies were attached as described<sup>13</sup>. After 'radioactive staining', the paper was washed six times with 1 l of PBS, dried and autoradiographed at  $-70^\circ\text{C}$  using preflashed X-ray film (Kodak XRP-5) and a fast tungstate intensifying screen (Ilford). The autoradiogram (a) was obtained after a 4-h exposure and is aligned with the stained gel (b). The lower molecular-weight radioactive material beneath the  $\mu$  chain band in the leftmost channel is a degradation product of 104E IgM.

presently known) nor the relative amounts of T lymphoma  $\mu$  RNA compared to its B cell (e.g. W231) counterpart provide an explanation for the absence of  $\mu$  polypeptides.

It therefore seems that post-transcriptional control of  $\mu$  polypeptide synthesis may operate in T lymphoma cells. Further evidence for the occurrence of untranslated  $C_\mu$  RNA comes from some of our recent observations with Abelson virus-transformed pre-B cell lines. Four lines contain  $C_\mu$  RNA but only one of them, 18-81, produces  $\mu$  chains (I.D.W., A.W.H. and D. J. Kemp, unpublished observations). Thus, in the B lineage, the ability to translate  $\mu$  RNA molecules may be

acquired during later states of differentiation. If the same programme were to apply to the T-cell lineage, then  $\mu$  polypeptide synthesis could be expected at a later stage of development than that represented by the T lymphoma lines of this study.

We thank Dr D. J. Kemp for making data available to us before publication and for critically reading this manuscript, and Drs K. Shortman and E. Siden for providing rabbit anti-IgM antiserum and the 18-81 cell line respectively. Sue Gherashe and Angela Apa gave excellent technical assistance.

## Methylation map of *Xenopus laevis* ribosomal RNA

B. E. H. Maden

Department of Biochemistry, University of Glasgow,  
Glasgow G12 8QQ, UK

One of the most enigmatic features of eukaryotic ribosomal RNA is the presence of many methylated nucleotides. The numbers of RNA methyl groups range from approximately 70 per ribosome in yeast<sup>1</sup> to over 100 in vertebrates<sup>2,3</sup>. Here it is shown that the methylated nucleotides in *Xenopus laevis* rRNA are broadly but non-uniformly distributed. In 18S rRNA 2'-O-methylations are partly concentrated in the 5' region and base methylations near the 3' end. In 28S rRNA methyl groups are infrequent in the 5' region, moderately frequent in the central region and abundant in an 1,100-nucleotide tract near the 3' end.

To map the methylated nucleotides rRNA was radioactively labelled in *X. laevis* cultured kidney cells. 18S or 28S rRNA was then hybridized to cloned restriction fragments of rDNA (Fig. 1) or to smaller, purified restriction fragments derived from the clones (see Fig. 3, below). As only part of the rRNA was complementary to each restriction fragment, the noncomplementary RNA could be eliminated by digestion with T<sub>1</sub> ribonuclease. The complementary rRNA was then eluted, examined by fingerprinting, and the methylated oligonucleotides in each region identified. (Limited, partial mapping data were previously obtained by this general method<sup>4,5</sup>.)

Figure 2 shows some representative fingerprints. Numerous further fingerprints were obtained covering all the regions and subregions in Fig. 3. As most methylated T<sub>1</sub> products occur once per molecule of 18S or 28S rRNA<sup>2,3</sup>, the presence or absence of particular products in different fingerprints was usually clearly recognizable, especially when autoradiographs of fingerprints which had been run simultaneously were superimposed. Additional criteria for sequence identification were alkaline hydrolysis followed by electrophoretic analysis of methylated components<sup>2,3</sup>, and use of the combined T<sub>1</sub> plus pancreatic ribonuclease fingerprinting system<sup>6,7</sup>. This system resolves, in the form of well separated digestion products, several methylated components that occur within high-numbered T<sub>1</sub> products that are not well resolved in Fig. 2.

Nearly all unimolar products mapped uniquely within a single rRNA region or subregion, and in general the relative molar recoveries were in good agreement with the yields previously determined for whole 18S or 28S rRNA. A few products hybridized to two adjacent rDNA fragments (see Table 1). In each case the most likely explanation is that the RNA methylated oligonucleotide is encoded across or very close to the respective restriction site in rDNA. There were no instances of methylated sequences cross-hybridizing to widely separated regions in rDNA. Of the few methylated oligonucleotides that occur more than once per 18S or 28S rRNA, approximately correct aggregate recoveries were obtained from the sub-region(s) in which the spots mapped.

The findings are summarized in Fig. 3 and Table 1. In 18S rRNA methyl groups occur in all subregions, but their distribution is strikingly non-uniform, especially when 2'-O-ribose methylation and base methylation are scored separately. This distinction is biologically important because during eukaryotic ribosome formation 2'-O-methyl groups are added very rapidly to ribosomal precursor RNA in the nucleolus<sup>2,8</sup> probably to nascent chains<sup>9</sup>, whereas the few base methyl groups in 18S rRNA are added later during ribosome maturation<sup>2,10</sup>. 2'-O-methyl groups are relatively much more abundant in the 5' part of the molecule than in the central or 3' parts. 60% of the 2'-O-methyl groups are in the 5' 40% of the molecule. In contrast, the dimethyl A sequence (product 30) is close to the 3' end<sup>4,11</sup> and the m<sup>6</sup>A sequence (product 34) is also in region III. The m<sup>7</sup>G sequence (product 49) is on the boundary between regions II and III, and the sequence containing the hypermodified base, am<sup>ψ</sup>, (product 37)<sup>10</sup> is within the rather large subregion IIb.

In 28S rRNA the distribution of methyl groups is quite different from that found in 18S rRNA. At the 5' end there is a long tract of about 900 nucleotides containing only one methylated component, Am-G. There is then a small cluster of methyl groups in region IVb and the first part of Va, followed by a 'trough' in the second part of Va. Near the middle of the molecule a group of 16 methyl groups occupies the first two parts of region Vb. There follows another, distinct trough between the first of two PvuII sites and the second PvuII site or possibly the adjacent HincII site. The next 1,100 nucleotides (regions Vc and VIa) contain by far the highest abundance and concentration of methyl groups in 28S rRNA—36 2'-O-methyl groups and four of the five base methyl groups, or 60% of the total 28S methyl groups in little over 25% of the molecule. Finally, the 200 nucleotides at the 3' end contain only one methyl group. These 28S findings confirm and much extend in detail those of Brand and Gerbi<sup>5</sup>.

28S rRNA possesses several sequences in which two or more methyl groups occur within a single T<sub>1</sub> ribonuclease oligonucleotide<sup>3</sup>. These multiply methylated sequences are distributed between the three larger-scale clusters. One such oligonucleotide occurs in region IVb (product 14, containing the

**Fig. 1** Slightly more than one repeat of *X. laevis* rDNA, showing cloning sites, cloned fragments and rRNA regions. Cloned fragments Xlr14 and Xlr11 have been described elsewhere<sup>4,5,11,22</sup> (Xlr)14B and 14A were subcloned from Xlr14 into pBR322 (ref. 23). Remaining fragments were subcloned into pBR322 in this work. Cloning sites in rDNA permit division of rRNA into following principal regions: I, 18S 5' end→PstI (628); II, 18S PstI→EcoRI (~950); III, 18S EcoRI→3' end (227); IV, 28S 5' end→BamHI (~1,100); V, 28S BamHI→EcoRI (~2,500); VI, 28S EcoRI→3' end (500). Numbers in parentheses are numbers of RNA nucleotides, determined from sequencing, hybridization and restriction data (refs 13, 23-25 and unpublished work of M. Salm, L. Hall and B.E.H.M.). NTS, ETS, ITS denote nontranscribed, external-transcribed and internal-transcribed spacers, respectively. NTS contains additional BamHI (ref. 22) and PstI sites not shown by Base notes.

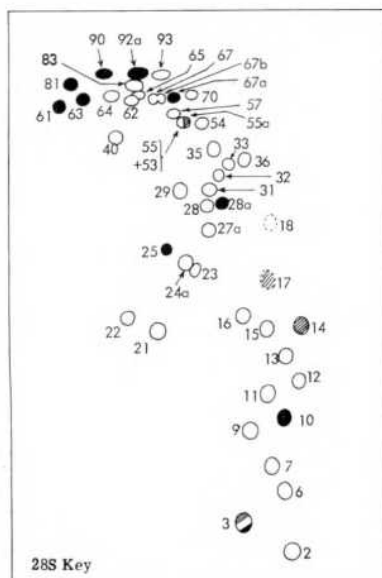

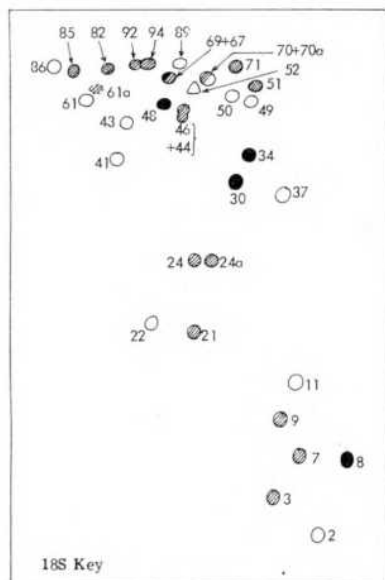

unusual, base-modified m<sup>1</sup>A), another in the adjacent part of region Va, two more in the first part of region Vb and three in regions Vc plus VIa. The central location of the triply methylated sequence, Am-Gm-Cm-A in region Vb, is of particular interest, as an identical component was once assigned to the 5' end of mammalian 28S rRNA<sup>12</sup>, although results from our laboratory did not support this assignment<sup>6</sup>.

The most striking feature of the methyl group distribution is its large-scale nonuniformity, both in 28S rRNA and to a lesser extent in 18S rRNA. Methylation requires recognition by methylases of specific sites in ribosomal precursor RNA or (for the few late methylations) in mature 18S rRNA. The recognition sites are evidently much more abundant in some regions of rRNA than in others. It seems likely that the frequencies of methylation sites in different parts of rRNA are somehow

related to other aspects of ribosome structure and function. Some indications of a possible link between rRNA methylation and biological function may be gained from the following. (1) The resolution of the methylation map is sufficient in many regions to permit accurate pinpointing of methyl groups in relation to sequence data obtained from rDNA<sup>13</sup>. This analysis is currently being extended for 18S rRNA with a view to definitive characterization of the methylation sites in this rRNA. (2) The rRNAs of several vertebrates yield similar fingerprints of methylated oligonucleotides to *X. laevis*, with a few distinguishing features<sup>3</sup>. It is therefore likely that the methylated sequences are similarly distributed along the primary structure of rRNAs in other vertebrates. (3) Gerbi and co-authors<sup>5,14</sup> have pointed out that much of the highly methylated region near the 3' end of *Xenopus* 28S rRNA is highly conserved between

**Fig. 2** T<sub>1</sub> ribonuclease fingerprints of regions of *X. laevis* methyl-labelled rRNA. *X. laevis* cultured kidney cells were labelled with sufficient [<sup>14</sup>C]-methionine (Amersham, ~50 mCi mmol<sup>-1</sup>) to permit growth for 3–4 generations, and 18S and 28S rRNA were prepared as described elsewhere<sup>6</sup>. A slight molar excess of the appropriate rRNA was hybridized to ~100 µg of linearized recombinant plasmid DNA containing fragment 14E for region I, 14F for region II and so on (see Fig. 1). Details of hybridization, trimming of hybrids with T<sub>1</sub> ribonuclease and recovery of T<sub>1</sub>-resistant, hybridized RNA are given in ref. 13. Fingerprinting was as described<sup>26</sup>. First panel on upper line shows diagram of whole 18S rRNA; fingerprint has been published<sup>3</sup>. Shaded spots (3, 7, 9...) are in region I (fingerprint in second panel), open spots (2, 11...) are in region II (third panel), filled spots (8, 30...) are in region III (last panel). Spots 44 and 46 usually co-migrate<sup>3</sup>, but have separated in (I). 61a is a faint component (0.3 M) which is not included in Table 1. First panel on lower line shows diagram of whole 28S rRNA; fingerprint has been published<sup>3</sup>. Shaded spots are in region IV (second panel), open spots in region V (third panel), filled spots in region VI (last panel). Spot 3 occurs in each of the three regions. Spot 17 (region IV) is almost certainly a derivative of spot 14 resulting from isomerization of m<sup>1</sup>A to m<sup>6</sup>A during hybridization at elevated temperature and subsequent elution<sup>7,27</sup>; individually the yields of the two spots varied but collectively they always amounted to two methyl groups (mA plus Am-C; Table 1). Spot 18 is recovered in low yield and is not included in Table 1. 83 in the key is a mixture of 83, 83a and 83b (Table 1); 93 in the key is a mixture of 93, 93a and probably another component, 93b, in Table 1. Products 85 upwards in 18S and 28S rRNA showed variable mobilities or streaking in T<sub>1</sub> fingerprints but were definitively mapped by additional criteria outlined in text.

Table 1 Methylated sequences in *X. laevis* rRNA

| 18S subregion    | Methylated sequences   | Methyl 2'-O, base | Length  | Methyl 2'-O, base | Length | 2'-O-methyl per 100N |

|                  |  | Total             | ~62 (5) | ~4,150            | 1.49   |                      |

The methylated sequences shown here are as reported in ref. 3, although the two low-yield products, 61a (18S) and 18 (28S), are not shown as they have not been precisely mapped. Most sequences longer than tetranucleotides are given only in part. Further details, where available, are in refs 3 and 13. The nomenclature (revised) is as follows: The former 18S spot 70 (ref. 3) has two components, now called 70 (region Id) and 70a (region IIc). Spot 89 is correct identification for a spot previously designated 87. Former 28S spot 67 has two components now called 67 and 67b (both in region Vc). Identification and mapping of product 93b are tentative. In regions Ia, IIa and III, products are listed in the order in which they appear in the sequence. In other regions they are listed in arbitrary order. In the last columns data are grouped to highlight main features of methyl group distribution, firstly by subregions, then by larger rRNA segments with differing methylation densities. Further details on experimental methods are given in Fig. 3 legend.

**Fig. 3** The general features of methyl group distribution and restriction fragments used. Restriction map is to scale and methyl groups were reliably assigned to each subregion, but precise locations within each subregion are so far known in only a few instances<sup>11,13</sup>. Closed circles denote 2'-O-ribose methyl groups, open circles denote base methyl groups, brackets denote multiply methylated oligonucleotides. Preparative hybridization required rDNA fragments at least a few hundred nucleotides long; shorter fragments did not adhere to nitrocellulose filters. There was no upper limit to useful fragment length, and presence of vector DNA (which adjoined many of the fragments in Fig. 3) did not cause spurious hybridization. As large quantities of restriction fragments were required (equivalent to ~100 µg of whole plasmid per  $M_{16}$ - $^{14}$ C) fingerprint separations were usually on sucrose gradients (10–25%, in 1 M NaCl, 0.001 M EDTA, 0.025 M Tris-HCl, pH 8); restriction enzymes which cut infrequently were chosen where possible, and several subregions were mapped by 'overlaps' (lower part of figure). Restriction digests were planned from published maps of rDNA<sup>24,25</sup>, unpublished data (below), map of pBR322 (ref. 28) and known orientation of rDNA insert. In the 18S gene, sites shown for PstI, SmaI and EcoRI are only sites for those enzymes. There are several HincII sites, those shown are next left of PstI and EcoRI sites respectively<sup>25</sup>. HincII digestion of appropriate plasmids yielded these short rDNA regions attached to an easily separated fragment of pBR322 DNA. In the 28S gene, sites shown for HincII, BamHI, BglII, SsrI, PvuII and EcoRI are only sites for those enzymes. There are several SmaI sites<sup>24,25</sup>; those shown are the last two in the gene. There are also several AluI sites<sup>24,25</sup>, the one shown is first in 28S gene. The SsrI and PvuII sites are subsets of AluI sites and were mapped in this work. They are the second and sixth or seventh AluI sites (SsrI) and the third and fourth AluI sites (PvuII). Left-hand sites defining SsrI, 700 and AluI, 700 are in ITS and 5.8S gene respectively in Xlr11. See ref. 24 for AluI map. After purification of rRNA fragments by preparation hybridization, most products were recovered in ~100 µg yield in T<sub>1</sub> ribonuclease fingerprints. Those marked (x2) or (x0.5) in Table 1 occur in approximately these frequencies. (0.5 M spots were treated as unimolar in the quantitative summary) Spot 37 and some of highest-numbered spots showed variable mobilities and yields in T<sub>1</sub> fingerprints. Smaller 'derivative' products occurred in good yields in combined T<sub>1</sub> plus pancreatic ribonuclease fingerprints. See ref. 7 for correlation between the two fingerprinting systems. A few products hybridized weakly to two adjacent fragments. In each case the probable explanation is that the methylated sequence occurs close to a restriction site. Spot 52 hybridized with region IIa and weakly with region Id. Sequence data (M. Salm and B.E.H.M., unpublished) place this sequence as next product to right of PstI site. Spot 49 hybridized with regions IIc and III. Data on RNA oligonucleotide are consistent with DNA sequence encompassing EcoRI site (M. Salm, L. Hall and B.E.H.M., unpublished). Spot 64 in 28S RNA hybridizes with region Vb and weakly with Va. Sequence G-A-U-Cm-U-U-G probably overlaps BglII site, (A)-G-A-T-C-T... One of the Gm-G residues in 28S RNA is probably close to second HincII site (demarcating regions Vb and Vc), it is not yet known on which side.

*Xenopus* and yeast, whereas the almost unmethylated region near the 5' end shows little sequence conservation between these distantly related eukaryotes. It will be extremely useful to determine at the level of nucleotide-sequence analysis the precise relationship between sequence conservation and secondary modification sites during eukaryotic rRNA evolution. (4) The only region of clear sequence homology so far identified between *Xenopus* 18S rRNA and *Escherichia coli* 16S rRNA is a short region at the 3' end<sup>11,14</sup>. This short, homologous region contains the dimethyl A sequence. The 5' one-third of *E. coli* 16S rRNA is completely unmethylated<sup>15,16</sup> in contrast to the highly 2'-O-methylated 5' one-third of *Xenopus* 18S rRNA.

## Structure of crystalline actin sheets

Ueli Aepli, Phillip Ross Smith\*, Gerhard Isenberg & Thomas D. Pollard

Although actin is one of the most abundant proteins found in nature, little detailed information about its molecular structure is available beyond the amino acid sequence<sup>1,2</sup>. Electron microscopy of negatively stained filaments combined with three-dimensional image reconstruction techniques have revealed the overall size and shape of the actin monomer at 25 Å resolution<sup>3-5</sup>. Higher resolution structural data can be expected from electron microscopy of two-dimensional crystalline arrays<sup>6,7</sup> and X-ray diffraction analysis of three-dimensional crystals<sup>8-11</sup>, but only very preliminary results have been reported so far. The original finding by Dos Remedios and Dickens<sup>4</sup> was that skeletal muscle actin forms microcrystals and tubes in the presence of the trivalent lanthanide gadolinium (Gd<sup>3+</sup>). We have modified and refined their conditions to obtain large crystalline sheets of *Acanthamoeba* actin and present here a model of the actin monomer in projection to 15 Å resolution. We have found that, depending on the ionic strength used, these sheets occur in three different forms: 'cylinders', 'square type' sheets and 'rectangular type' sheets. These different polymorphic forms are built from the same fundamental two-dimensional crystalline actin lattice, which we call the 'basic sheet'. The present concerns the structural analysis of these basic sheets; the crystal polymorphism will be discussed in detail elsewhere (U.A. *et al.*, in preparation). Furthermore, in addition to demonstrating that actin is an elongated globular molecule with a pronounced asymmetric shape in and perpendicular to the plane of the sheet, our results indicate that these crystalline actin sheets might be suitable for three-dimensional structure determination by low-dose electron microscopy of unstained specimens<sup>12,13</sup> to at least 10 Å resolution.

An electron micrograph of a negatively stained basic sheet from an opened-up cylinder (Fig. 1A) reveals that these sheets

are made of a near-rectangular lattice with average lattice parameters  $a = 56.5$  Å,  $b = 65.5$  Å and  $\gamma = 85.5^\circ$  (average of 60 sheets). Figure 1B displays an optical diffraction pattern recorded from a circular area of the micrograph including about 1,000  $56.5 \times 65.5$  Å unit cells. The fact that strong  $(33 \text{ Å})^{-1}$  second order reflections are visible along  $b'$ , with the  $(65.5 \text{ Å})^{-1}$  first order reflections being almost completely absent, is consistent with the observation of a pronounced 33 Å pseudo-repeat along  $b$  in the images (see Fig. 1A), indicating that there might be two molecules per unit cell, related to one another by a two-fold axis of symmetry. Optical diffraction analysis of basic sheets indicates that the long-range order can extend to 5,000 Å in both directions within the plane of the sheet, with sharp diffraction spots extending out to  $(15 \text{ Å})^{-1}$  (see Fig. 1B for example  $(\pm 1, \pm 4)$  reflections). We have found right- and left-handed basic sheet lattices with about equal frequencies with negatively stained specimens. However, the sheets appearing left-handed on the grid (see Fig. 1A) invariably showed better structural preservation and higher resolution detail. As is illustrated in Fig. 2, the handedness of the basic sheet observed on the grid depends on which of the two sheet surfaces is in contact with the carbon support film on adsorption.

Basic sheets prepared for electron microscopy by adsorption freeze-drying and shadowing<sup>14,15</sup> showed two surface topographies. One surface was smooth and regular, with a near-rectangular right-handed lattice texture (Fig. 2A) and average lattice parameters  $a = 55$  Å,  $b = 63.5$  Å and  $\gamma = 86.5^\circ$  (average of 40 regular-looking sheets). The other surface appeared coarse and irregular, with no indication of a lattice texture, and showed a granularity similar to that found in the background (Fig. 2B). Occasionally, basic sheets folded over, allowing the two distinct surface topographies to be seen simultaneously (Fig. 2C). Optical diffraction patterns recorded from the regular surface of shadowed basic sheets yielded the  $(55 \text{ Å})^{-1}$  and  $(63.5 \text{ Å})^{-1}$  first order reflections along  $a'$  and  $b'$ , respectively, with no indication of the  $(32 \text{ Å})^{-1}$  second order reflections along  $b'$  observed with negatively stained sheets (Fig. 1B). This must be due to the inability to resolve the two molecules in the unit cell by our freeze-drying and shadowing technique. In contrast, basic sheets with the irregular surface topography did not produce any reciprocal lattice reflections on optical diffraction. From the lengths of the shadows cast at the edges of the sheets we calculated their average thickness to be 45 Å (average of

**Fig. 1** A, Electron micrograph of a negatively stained actin basic sheet arising from an opened-up cylinder. Basic sheets were prepared as follows: *Acanthamoeba* G-actin, purified by a modification of the methods described<sup>16,17</sup>, was diluted to  $1.5 \text{ mg ml}^{-1}$  and subsequently dialysed against  $2.5 \text{ mM}$  imidazole,  $\text{pH } 7.25$  ( $4^\circ\text{C}$ ),  $0.25 \text{ mM}$  dithiothreitol (DTT) and  $0.005\%$   $\text{NaN}_3$  for  $5 \text{ h}$  at  $4^\circ\text{C}$ . The sample was then spun in a Beckman Airfuge for  $15 \text{ min}$  at  $130,000\text{g}$  to remove aggregated material and the supernatant dialysed against  $2.5 \text{ mM}$  PIPES,  $\text{pH } 7.00$  ( $4^\circ\text{C}$ ),  $150 \text{ mM}$  KCl,  $0.25 \text{ mM}$  DTT,  $0.005\%$   $\text{NaN}_3$  and  $\text{GdCl}_3$  (molar ratio  $\text{Gd}^{3+}$ : actin  $\geq 6:1$ ) for  $15 \text{ h}$  at  $4^\circ\text{C}$ . At this stage the sample consisted of a mixture of filaments ( $30\text{--}50\%$  of aggregated material), rectangular and square type sheets, and cylinders (U. A. *et al.*, in preparation). A low-speed pellet ( $5,000\text{g}$  for  $5 \text{ min}$ ) of this material was resuspended in one-third volume assembly buffer (see above) and immediately dialysed against  $2.5 \text{ mM}$  PIPES,  $\text{pH } 7.00$ , and  $0.005\%$   $\text{NaN}_3$  for at least  $12 \text{ h}$  at  $4^\circ\text{C}$ . The sample was then spun for  $10 \text{ min}$  at  $5,000\text{g}$  and the pellet resuspended in the same volume  $2.5 \text{ mM}$  PIPES,  $\text{pH } 7.00$  ( $4^\circ\text{C}$ ), and  $0.005\%$   $\text{NaN}_3$ . On dilution of this material to  $\leq 0.75 \text{ mg ml}^{-1}$  with the same buffer, basic sheets started peeling off the rectangular and square type sheets, and the cylinders opened up into basic sheets when diluted material was left for a few hours at  $4^\circ\text{C}$ . For electron microscopy,  $2\text{-}\mu\text{l}$  drops were adsorbed for  $60 \text{ s}$  to carbon-coated  $400\text{-mesh}$  per inch copper grids which were rendered hydrophilic by glow discharge in a reduced atmosphere of air. The grids were then washed for  $30 \text{ s}$  on several drops of distilled water and stained for  $30 \text{ s}$  on several drops of  $0.75\%$  uranyl formate,  $\text{pH } 4.25$ . Electron micrographs of these specimens were recorded on Kodak 4463 Electron Image Film in a Zeiss EM 10A electron microscope at  $\times 50,000$  nominal magnification and developed for  $4 \text{ min}$  in  $1:2$  times diluted Kodak D-19 developer. To minimize the accumulated electron dose on the areas to be photographed, a beam rocking technique<sup>18</sup> was used. The example shows a basic sheet with its regular surface in contact with the carbon support (see text and Fig. 3), and therefore its near-rectangular lattice appears left-handed (indicated by the lattice vectors **a** and **b**). Scale bar,  $1,000 \text{ \AA}$ . B, Optical diffraction pattern recorded from a circular area of the electron micrograph shown in A including about  $1,000$  unit cells. The reciprocal lattice vectors corresponding to the  $56.5 \times 65.5 \text{ \AA}$  near-rectangular lattice have been drawn to scale in the central inset. Scale bar,  $(20 \text{ \AA})^{-1}$ .

24 sheets), suggesting that the basic sheets are spanned by one actin molecule. The two distinct surface topographies of the basic sheets reflect two things: (1) the actin monomer must have a very asymmetric shape in the direction perpendicular to the plane of the sheet, and (2) all actin molecules are packed with the same polarity perpendicular to the plane of the sheet.

We have computer-filtered several micrograph areas containing well preserved negatively stained basic sheets, and have obtained the quaternary structure of the actin molecule within the sheet, and its overall size and shape in projection to  $15 \text{ \AA}$  resolution. The average unit cell morphology obtained from five different  $12 \times 10 \text{ } 56.5 \times 65.5 \text{ \AA}$  unit cell areas chosen

**Fig. 2** Electron micrographs of freeze-dried and shadowed basic sheets exhibiting the two different surface topographies. Samples of unfixed material were prepared for electron microscopy by the adsorption freeze-drying technique described elsewhere<sup>14,15</sup>. Unidirectional shadowing of the specimens was done with platinum from an electron gun at an elevation angle of about  $30^\circ$ . A, Example of a sheet displaying a regular, right-handed near-rectangular lattice surface (as indicated by the lattice vectors). B, Example of a sheet showing an irregular surface with no indication of a periodic lattice. C, Example of a folded-over sheet simultaneously exposing its two surfaces. The arrows in A, B and C indicate the direction of metal shadowing. Scale bar,  $1,000 \text{ \AA}$  (for A, B and C).

**Fig. 3** A contour plot showing the average two-fold symmetrized unit cell morphology obtained from five different electron micrograph areas of computer-filtered negatively stained actin basic sheets. All five sheets selected for filtering were left-handed (see text and Figs 1, 2). The electron micrographs were digitized with an Optronics P-1000 microdensitometer using a 50- $\mu\text{m}$  square raster, from photographic enlargements onto Kodak 4147 Plus-X pan film to give an effective sampling rate of 3.25 Å. Computer filtering was performed essentially as described previously<sup>19,20</sup> using  $12 \times 10$   $56.5 \times 65.5$  Å near-rectangular unit cell sheet areas. The filtered unit cells were two-fold symmetrized after searching for the best symmetry centre<sup>19,21</sup>: the power loss on two-fold symmetrization averaged to 2.1% over the five samples. The filtered and two-fold symmetrized unit cells from the five samples were then aligned with respect to their two-fold centres of symmetry and summed to give the average unit cell morphology shown. The near-rectangular unit cell (as indicated by the lattice vectors **a** and **b**) contains two actin molecules related to one another by P2 symmetry. Actin dimers and monomers are indicated by the light and dark shaded regions, respectively, in the right-hand side of the figure. The broken line marks the longer axis of the actin monomer, and is defined through the major and minor peak of the subunit in projection. Scale bar, 50 Å.

from four different micrographs is shown in Fig. 3. The following reproducible features were observed. (1) The  $56.5 \times 65.5$  Å near rectangular unit cell contains two actin molecules which are related to each other by a two-fold axis of symmetry perpendicular to the plane of the sheet (space group P2). (2) The actin monomer is elongated and measures about  $56 \times 33$  Å in projection, with its longer axis (indicated by a broken line) being tilted by about  $23^\circ$  with respect to the lattice vector **a**. (3) The projected mass density of the actin subunit possesses a pronounced asymmetry with a major and a minor peak along its longer axis. (4) The negative stain accumulates as a distinctive 2-and-1 pattern between columns of actin dimers.

The unit cell parameters of the basic sheets are in agreement with those determined previously by optical diffraction of negatively stained skeletal muscle actin tubes<sup>7</sup>. The overall dimensions of the actin monomer are similar to those obtained from three-dimensional reconstructions of average actin filaments computed by deconvolution from filament paracrystals<sup>3</sup>. Moreover, the distinct asymmetric shape of the subunit within and perpendicular to the plane of the basic sheet is consistent with the polarity of the actin monomer found by three-dimensional reconstruction of individual actin filaments<sup>5</sup>. A more quantitative comparison with the actin filament structure must await completion of a three-dimensional map of the molecule computed from tilted views of the crystalline sheets. However, the quaternary structure of the actin molecules in the basic sheet differs substantially from their packing in the filament. Although it is possible that the head-to-tail bonds between actin molecules are similar in the sheets (for example along **a**) and the filaments (for example along a single strand), the lateral associations cannot be the same in the two cases. In the sheets, adjacent rows

of subunits have opposite polarity, whereas in filaments the two strands have the same polarity with respect to the filament axis. Consequently, the assembly of the basic sheets cannot be explained as an 'unwinding' of the double-helical filaments into linear double strands, followed by a side-by-side association of these linear double strands.

From the size and long-range order of the crystalline actin sheets described here, we are confident that a three-dimensional model of the actin molecule can be determined to at least 10 Å resolution by low-dose electron microscopy and three-dimensional reconstruction of tilted views of unstained specimens<sup>12,13</sup>. Finally, it might be possible to decorate basic sheets stoichiometrically with actin-interacting proteins such as myosin S-1, troponin, gelation factors, profilin, DNase I and 5'-nucleotidase, and thus to map the binding sites for these molecules on the three-dimensional model of actin.

We thank Dr V. G. Allfrey for allowing us to use his Optronics P-1000 microdensitometer. ## Helix packing and subunit conformation in horse spleen apoferritin

George A. Clegg, Robert F. D. Stansfield, Philip E. Bourne & Pauline M. Harrison

Department of Biochemistry, The University, Sheffield S10 2TN, UK

An electron density map of horse spleen apoferritin at 0.28-nm (2.8 Å) resolution and its preliminary interpretation have been described previously<sup>1</sup>. Rigorous examination of this and newer maps at the same nominal resolution but calculated from more extensive data sets, including model building in a Richards' comparator<sup>2</sup>, now allows us to report on structural features in more detail. We list inter-helical angles within and between neighbouring subunits, and describe a new short region of inter-subunit anti-parallel pleated sheet. A short section of electron density not properly accounted for in the first model has also been found. We also report on two alternative ways of connecting helical regions which account almost equally well for the observed electron density, and we assess these two alternative conformations and compare them with the conformations of other known proteins.

The iron storage molecule ferritin consists of a protein shell comprising 24 subunits in 432 symmetry surrounding an inorganic 'core' of hydrated ferric oxide-phosphate. Horse

**Fig. 1** Stereoscopic views of connected  $\alpha$ -carbon coordinates for well established regions in an apoferritin dimer. *a*, The view down a molecular diad from outside the molecule. The four major helices A, B, C, D in the leftmost subunit occur: above right, below right, above left and below left, respectively. *b*, 'End-on' view perpendicular to the diad and parallel to a molecular triad. The four major helices A, B, C, D in the leftmost subunit occur: below right, above right, below left and above left, respectively. The atomic positions used here and in Fig. 2 have regular geometry and are faithful to the electron density map, but may not be correct in every detail.

spleen apoferritin (subunit molecular weight 19,000) crystallizes from  $\text{CdSO}_4$  solution in space group  $F432$  with  $a = 18.40$  nm (184.0 Å). The asymmetric unit contains a single subunit. Electron density maps show clearly that each subunit consists of a bundle of four long helices lying parallel or anti-parallel to one another; together with two much shorter helices and stretches of irregular conformation. It is in the inter-helical connecting regions that the electron density is weakest and where difficulties are experienced in tracing the course of the polypeptide chain unambiguously. Preliminary sets of  $\alpha$ -carbon and carbonyl oxygen atomic coordinates have been measured in the Richards' comparator and used to derive regularized sets of coordinates for main chain and  $\beta$ -carbon atoms.

We will first describe the regions which we consider to be reasonably well established. These are the long helices A, B, C and D, containing approximately 27, 25, 28 and 20 amino acid residues respectively, and two short helices, P, 7 residues (formerly described as a helical turn), and E, comprising about 10 residues. The total number of helical residues (117) accounts for about 68% of the main chain density. Helix B uniquely seems to contain an irregularity near the middle of its length, and N-terminal regions of helices C and D seem to be fitted best by one to two turns of  $3.0_{10}$  helix. There is also good density for the sharp turn connecting C and D, for the long loop L and (less so) for the connecting regions between D-P to E. The directions of the helices are confirmed to be those previously assigned, and angles between pairs of helices are given in Table 1. Among the four major helices of one subunit, adjacent anti-parallel pairs lie within the range  $166 \pm 5^\circ$  to one another, and diagonally opposite parallel pairs are inclined at  $\sim 17^\circ$ . The four helices are thus related by 222 pseudo-symmetry with pseudo-diads passing between helical pairs A, C and B, D and between C, D and A, B and a third lying nearly parallel to the long axes of the helices (and this is the long axis of the subunit). In the apoferritin 432 quaternary structure, pairs of subunits related by molecular

diads lie with their long axes anti-parallel. Angles relating all pairs of helices within this 'dimer' are given in Table 1. Interestingly, angles relating neighbouring anti-parallel helices A, A' and B, B' related by the molecular two-fold axis are similar to those within the subunit, and the same is true of the diagonally related pairs A, B' and B, A'. Thus, a complete system of eight helices is formed comprising two layers, each of which contains four anti-parallel helices, and this system itself has pseudo-222 symmetry.

In Fig. 1 stereo views of the helices and other well established regions within the dimer are shown as connected  $\alpha$ -carbon diagrams down the diad (Fig. 1*a*) and approximately end-on to the major helices, perpendicular to the diad and parallel to a molecular three-fold axis (Fig. 1*b*). It can be seen in Fig. 1*b* that the four major helices within a single subunit together show a left-handed twist when viewed down their lengths, whereas the two pairs of A and B helices near the diad are arranged so that diagonally related pairs A, B' and B, A' converge at opposite

**Fig. 2** Illustration of the subunit packing around a molecular triad, showing three dimers (*a*) and around a molecular tetrad, showing four dimers (*b*).

ends of the arrangement. The dimer has a rather flat, lozenge shape, and the overall arrangement within the molecule is such that each dimer lies roughly on the face of a rhombic dodecahedron with subunit axes nearly parallel to one pair of edges of the rhomb. A better molecular envelope is a rhombic dodecahedron truncated to give a polyhedron inscribable within a sphere. Figure 2 shows the packing of three dimers around a three-fold axis (a) and four dimers around a four-fold axis (b), with  $\alpha$ -carbon coordinates used for one subunit only.

Another feature of the structure which has become apparent as a result of model building is a short stretch of anti-parallel  $\beta$ -pleated sheet which joins the loops (L) from neighbouring diad-related subunits over a region around the two-fold axis. Four hydrogen bonds are formed, involving a total of five residues in each subunit, and the  $\beta$ -strands exhibit a characteristic right-handed twist when viewed along their length<sup>3</sup>. This pleated sheet structure lies on the outside surface of the molecule (see Fig. 1) at a region of intermolecular contact.

The two alternative ways of joining the defined segments which best fit the electron density are as follows. Each of these starts with the same extended N-terminal sequence of about 12 residues preceding the A helix. Only four residues were previously described and a section of electron density, relatively isolated but tenuously connected to these residues, was missed in our first interpretation. The C-terminal end of A may be connected through a short turn to the N-terminus of either B (as in our original interpretation) or C. The peptide segments are joined subsequently in order A  $\rightarrow$  B  $\rightarrow$  L  $\rightarrow$  C  $\rightarrow$  D  $\rightarrow$  P  $\rightarrow$  E (Fig. 3a) or A  $\rightarrow$  C  $\rightarrow$  D  $\rightarrow$  P  $\rightarrow$  E  $\rightarrow$  B  $\rightarrow$  L (Fig. 3b). Note that all the interhelix connections in both alternative conformations, except for the long loop joining B and C in Fig. 3a, exhibit the usual right-handed character<sup>4</sup> (viewed parallel to the helix-pair contact vector). The alternative subunit conformations are shown schematically in Fig. 3a and b, respectively, and in c and d using the mode of representation of Levitt and Chothia<sup>5</sup>. The differences between these connectivities depend on whether density beyond A is attributed to side-chain or main-chain density, and whether the short tail at the C-terminus of E is free, leaving the C-terminus of the molecule inside the shell, or whether it is joined to B. Overall, the chain length seems to be a few residues longer than in our earlier description.

The packing of the four long helices in the apoferritin subunit resembles that of several other proteins, including myo-

**Table 1** Angles between the helices within an apoferritin dimer

| A |     | 154 | 29  | 17  | 156 | 142 | 41  |
| B | 171 |     | 151 | 159 | 20  | 33  | 145 |
| C | 170 | 16  |     | 174 | 20  | 48  | 129 |
| D | 18  | 168 | 161 |     | 171 | 138 | 42  |
| P | 62  | 119 | 126 | 51  |     | 88  | 90  |
| E | 116 | 62  | 57  | 130 | 172 |     | 94  |

A, A' and so on are related by the symmetry ( $z, -y, x$ ). Intra-subunit angles, in degrees, are found in the leftmost (lower) triangle and inter-subunit angles on the (upper) right.

haemerythrin<sup>6,7</sup>, haemerythrin<sup>8,9</sup>, tobacco mosaic virus<sup>10</sup>, cytochrome *b*<sub>562</sub> (ref. 11) and cytochrome *c'* (P. Weber, personal communication). Moreover, angles between helices shown in Table 1 closely resemble those in myohaemerythrin<sup>6</sup>, and the bundle of four helices in all these structures apparently has a left-handed twist. It does seem that this mode of helical packing may indeed be considered as a stable 'super-secondary structure' as suggested earlier<sup>12</sup>. Furthermore, the subunit relationship in the apoferritin shell dimer closely resembles that in cytochrome *c'* (P. Weber, personal communication). An attractive feature of the alternative conformation shown in Fig. 3b is that the connectivity closely resembles that in the other proteins. However, a feature of the connectivity of Fig. 3a, which is attractive from another point of view, is that this subunit structure seems to be constructed from two approximately equal parts (A to L inclusive and C to E inclusive, comprising sequences of approximately equal length) which could conceivably have arisen from gene duplication. Some support, however slight, for this suggestion is the structural similarity of the A, B and C, D helical pairs and the finding of mercury sites (and therefore presumably cysteine) near the N-terminal ends of helices B and D. An unequivocal assignment of the apoferritin subunit conformation awaits the completion of the amino acid sequence by Crichton and colleagues, and the extension to higher resolution and refinement of the structure. Although it has been reported earlier that the C-terminus is available to carboxypeptidase action, this has not been confirmed in recent work on human liver ferritin (J. M. Sowerby and J. E. Fitton, unpublished preliminary observation). This latter result would favour Fig. 3a rather than b. Partial proteolysis gives rise to two fragments of molecular weights approximately 7,500 and 11,000, the smaller of which is thought to include the N-terminus<sup>13,14</sup>. Such fragments could arise in either connectivity by splitting at the BL connection in Fig. 3a or at the CD turn in b.

We thank the SRC, MRC, the Royal Society and the Blood Research Fund for support, and Mr Graeme Dolderson for technical assistance.

**Note added in proof:** Details of the cytochrome *c'* structure have now been published<sup>15</sup>, and a more detailed comparison of the 4- $\alpha$ -helical proteins has been made<sup>16</sup>. Completion of the amino acid sequence of horse spleen apoferritin has also recently been reported<sup>17</sup>.

# MATTERS ARISING

## Evolution of the orang-utan

SMITH AND PILBEAM<sup>1</sup> have argued that "the available evidence... justifies the concept of a Pliocene orang-utan ancestor at least as terrestrial as the modern chimpanzee". It is, however, questionable whether they have established their thesis as equally, or more, plausible than the one they wish to replace (that the ancestral lineage of orang-utans was arboreal).

The authors have used both palaeontological and neontological records, but their arguments are unconvincing. First, there are no unequivocal data on the body sizes of Pleistocene orang-utans so that inferences on arboreality or terrestriality are tenuous. Although Smith and Pilbeam acknowledge the difficulty of drawing conclusions about body size from tooth size alone when considering subfossil orang-utan populations, they conclude that mid-Pleistocene mainland forms were larger-bodied and hence less arboreal than the extant form. The basis for such a conclusion is not evident. Second, plausibility alone does not constitute empirical (or theoretical) support for a thesis. Smith and Pilbeam suggest that it is plausible to view the large body size and marked sexual dimorphism of living orang-utans as remnants of a more terrestrial pattern. This is a possibility but they offer no direct support. Thus there is no reason to consider this alternative of greater importance than any other (sexual selection, niche separation, and such) that may have an influence on whether or not animals are terrestrial. Third, Kay<sup>2</sup> has shown that (1) there is no relationship between tooth enamel thickness and arboreality or terrestriality, and (2) thick enamel, as found in *Pongo*, seems to be associated with the consumption of hard fruits, nuts and seeds. This weakens arguments by Smith and Pilbeam that ancestral orang-utans may not have been arboreal frugivores.

If there are data that do not support a particular hypothesis, then the inconsistency should be explained. The postcranial anatomy of living orang-utans is the least equivocal source of data on possible "remnants... of a more terrestrial pattern". Morphological studies of orang-utan cheiridia<sup>3</sup>, wrist<sup>4</sup>, and hip and thigh<sup>5</sup> have all revealed marked specializations consistent with arboreal progression in a large-bodied primate. No features suggesting adaptations for terrestrial locomotion, present or past, have been reported. Smith and Pilbeam have not accorded these data the attention they deserve, nor explained why extant orang-utans should not display evidence of terrestriality in an ancestral form. It is unclear, for example, whether the authors postulate a stage of terrestriality so brief

that terrestrial adaptations had not time to evolve, or, if arguing for a longer period of terrestriality, whether the return to arboreal progression was to have been accompanied by an exact reversal of evolutionary changes.

Despite the available fossil evidence suggesting that "typical Neogene hominoids (including our hypothetical Pliocene orang-utan) were probably... woodland creatures", one cannot yet eliminate the possibility that this is a simple artefact of the still very limited fossil record. Similarly, there is no reason to expect that all fossils displaying an affinity to extant forms represent populations directly ancestral to living species. It may be worthwhile to consider the possibility, for example, that the mid-Pleistocene orang-utans represented by fossil teeth were a related, but not ancestral, species. Until the competing hypotheses of arboreality or terrestriality can be tested by unequivocal data from the fossil record, they must be considered viable alternatives.

I thank H. McHenry, P. Rodman and L. Scott for reading an earlier version of this manuscript.

SMITH AND PILBEAM REPLY—We do not know whether Miocene ancestors of the orang-utan were arboreal or terrestrial, and evidence marshalled in favour of either hypothesis is tenuous at best. Nevertheless, it seems to us that hypotheses for hominoid evolution generally have assumed with confidence that the orang lineage has always been arboreal. In offering evidence for the possibility of a terrestrial ancestor, our purpose was also to lead others to re-evaluate the supposed evidence for arboreality. We completely agree with Temerin's conclusion that arboreality and terrestriality "must be considered viable alternatives".

## Noradrenergic transmission

I WISH to raise two points concerning the discussion and conclusion in a recent report by Hirst and Nield<sup>1</sup>.

First, evidence quoted to illustrate that a portion of sympathetic postganglionic transmission is resistant to adrenoreceptor antagonists was derived from work on rodent vasa deferentia: the authors had concluded that in these tissues a component of the motor transmission was 'non-adrenergic' (refs. 2-5). From the reported results<sup>1</sup>, however, noradrenergic transmission resistant to  $\alpha$ -adrenoreceptor antagonists is postulated. This conclusion may be justified in the case of the arteriolar preparation under study and, if so, constitutes an important observation. However, if this is offered as an explanation for the 'non-adrenergic' component of transmission in vas deferens, it should be noted that all previous reports quoted as having supported this latter concept, did so not only on the evidence of resistance to antagonists but also because the response persisted after depletion of noradrenaline by reserpine, for example, to less than 1% of control levels<sup>6</sup>. Furthermore, responses persisted even after chemical sympathectomy when virtually all adrenergic nerve terminals had been removed<sup>7</sup>. In contrast, the 'conventional', adrenergic,  $\alpha$ -blocker-susceptible component was completely absent following reserpine or chemical sympathectomy<sup>7</sup>. If allowance for this adrenergic component in the control is made, the 'non-adrenergic' response is not reduced at all following the latter treatments<sup>2,8</sup>. There is, therefore, no evidence to connect this response in vas deferens with noradrenaline or noradrenergic nerves. To associate this with a discussion of the postulated mechanism in arteriolar muscle can only attract irrelevant criticism of the latter. It is also possible that the intracellular excitatory junctional potential and the 'non-adrenergic' contraction of the muscle layers reflect different cellular processes.

Secondly, the conclusion that there are 'two populations of excitatory receptors for noradrenaline in arteriolar smooth muscle' could be confused with the other recent evidence for two distinct types of excitatory  $\alpha$ -adrenoreceptor on vascular and non-vascular smooth muscle<sup>9,10</sup>; in this case, each response was blocked by the appropriate antagonist<sup>9-11</sup>. Furthermore, in contrast to the newly reported observation on arteriolar muscle<sup>1</sup>, the pressor response to sympathetic nerve stimulation was even more sensitive to blockade by the  $\alpha_1$ -adrenoreceptor antagonist, prazosin, than was the response to exogenous noradrenaline<sup>11,13</sup>. The 'phentolamine-resistant' effect of

noradrenaline<sup>1</sup> may thus point to a 'third' excitatory mechanism for noradrenaline. This may be supported by the observation that a small, residual, pressor response to catecholamines remains even after combined  $\alpha$ - and  $\beta$ -adrenoreceptor blockade<sup>12</sup>.

**HIRST AND NEILD REPLY**—We take the view that there are many similarities between the mechanisms of excitatory transmission in arterioles and vasa deferentia of guinea pigs. Both are innervated by catecholamine-containing nerves which when stimulated cause an excitatory junction potential (e.j.p.) in the underlying smooth muscle. The e.j.ps recorded from both tissues are to all intents and purposes identical<sup>1,2</sup>; e.j.ps from both tissues are rapidly reduced in amplitude by guanethidine and persist in high concentrations of adrenergic blocking agents. We consider that the failure of  $\alpha$ -blockade in arterioles arises because the neuronally released transmitter activates receptors which are unlike  $\alpha$ -receptors. In our preparation we are able to mimic the action of the neurotransmitter only when noradrenaline is applied to specific regions of the muscle; until similar experiments have been conducted on vas deferentia it seems unnecessary to reject the hypothesis that noradrenaline is the primary transmitter substance<sup>3-6</sup>.

McGrath rightly points out that some of the authors who take the view that a second unknown transmitter is released in addition to noradrenaline, base their opinion on further experiments in which tissue noradrenaline was in some way reduced<sup>3,6</sup>. A common method is by prior treatment with reserpine, which dramatically reduces but does not eliminate tissue noradrenaline<sup>7</sup>. However, it is by no means clear that a dramatic reduction in tissue noradrenaline leads to an equally dramatic reduction in the actual amount of noradrenaline released per nerve impulse<sup>8</sup>.

Concerning McGrath's second point, we did not mean to imply that arteriolar smooth muscle contained two distinct populations of  $\alpha$ -receptors, although this may well be the case. We stressed that the 'junctional' receptors that we were able to activate by noradrenaline were completely different from  $\alpha$ -receptors. To avoid the possibility of confusion it might perhaps be more appropriate to call the 'junctional' receptors  $\gamma$  gamma-receptors.

## Germ-line deletion of genes coding for self-determinants

JEMMERSON AND MARGOLIASH's article<sup>1</sup> raises provocative questions about immunological unresponsiveness to self-antigens. They found that the autoantigenic sites on rabbit cytochrome *c* correspond to those regions in the molecule where other mammalian cytochromes *c* differ, and suggested that archaic genes coding for V-region specificities of immunoglobulin recognizing shared portions of the cytochrome *c* molecule were eliminated by evolutionary pressures. This would result in immunologically silent peptide sequences, there remaining mainly V genes for the more recently evolved species-specific determinants. Thus, one mechanism of self-tolerance would be evolutionary germ-line deletion of V genes coding for specificities against self-molecule determinants.

Previous studies by one of us (N.R.R.) were directed to the antigenic properties of thyroglobulin in rabbits<sup>2</sup>. Two sorts of autoantibodies in rabbits were compared, those induced by immunization with rabbit thyroglobulin and those induced by immunization with foreign thyroglobulins, such as those of hog or beef. The first kind of autoantiserum resembled the rabbit antisera to rabbit cytochrome *c* described by Jemmerson and Margoliash. Tested for reaction with rabbit thyroglobulin, the rabbit thyroglobulin readily absorbed all reaction, whereas the hog (or beef) antigen removed only a small part of the antibody content. We concluded that

the rabbit preferred to form antibodies to the non-shared antigenic determinants of thyroglobulin.

In contrast, rabbits immunized with hog thyroglobulin showed relatively weak reactions with rabbit thyroglobulin, and these reactions could be absorbed equally well with hog, beef and rabbit thyroglobulins. Thus, autoantibodies induced by foreign thyroglobulin are directed mainly to the shared antigenic determinants of thyroglobulin.

On the basis of absorption behaviour, then, we could distinguish two types of autoantibodies. Those elicited by thyroglobulin of the same species were directed primarily to species-specific determinants, whereas the autoantibodies evoked by foreign thyroglobulins reacted mainly with the shared antigenic determinants. Of further interest, rabbits immunized with rabbit thyroglobulin showed severe lesions of thyroiditis. Only after repeated injections were even mild lesions seen in rabbits given foreign thyroglobulin.

The basic protein of myelin (BPM), a linear-folded protein without a tertiary structure, is another well characterized autoantigen. There are some 170 amino acid residues, and the sequences for the molecule of several mammalian species reveal a number of substitution sites. Because immunization with BPM induces experimental autoimmune encephalomyelitis (EAE) in all species studied, attention has focused on the capacity of BPM, and various peptides derived from it, to induce disease. The review by Bergstrand<sup>3</sup> indicates that different portions of the BPM molecule have greatly differing potency in terms of induction of (1) EAE, (2) cell-mediated immunity and (3) humoral antibody.

In the induction of EAE, which requires the participation of a T-cell response, detailed studies have defined the different amino acid sequences in the homologous proteins which induce EAE in different species. Minor sequence substitutions have an enhancing effect, for example, the encephalitogenic Ser-Thr substitution at residue 79 for the rat<sup>4</sup>, with other changes abrogating activity<sup>5</sup>.

With heterologous BPM injected into rabbits, one of the main determinants of humoral antibody was identified in the region 90-116 (ref. 6), and this does not vary between mammalian species. Unfortunately, relatively little information is available on the amino acid sequence(s) involved in the homologous response. Studies by microcomplement fixation assays in the rabbit<sup>7</sup> could be interpreted as showing a pattern of cross-reactivity between homologous and heterologous BPM equivalent to that described above for thyroglobulin. In particular, when rabbits were immunized with rabbit BPM, the antibody was predominantly reactive with rabbit BPM but with extensive cross-reaction with BPM of other species. It is assumed, although not

directly tested, that rabbit antibody to BPM is directed to the invariant 92–116 sequence.

Thus for thyroglobulin and BPM, genes specifying reactions to shared determinants do not seem to be eliminated by evolutionary pressures. However, examination of autoantigens in the light of the concept of Jemmerson and Margoliash would be interesting with respect to association of autoimmunity with disease.

**JEMMERSON AND MARGOLIASH REPLY**—A serious problem with the comparative study of protein antigens of unknown amino acid sequence and spatial structure is that one tends to invoke qualitative all-or-none differences, based on the particular antibody-binding test used, when in fact the differences may be merely quantitative. Thus, in the experiments on thyroglobulin cited by Mackay, Rose and Carnegie, it is possible that rabbit thyroglobulin injected into rabbits does not elicit antibodies which bind to hog or beef thyroglobulin because determinant sites on the rabbit protein, which would elicit such cross-reactive antibodies, bind too weakly to the rabbit immune system to effect the needed cell stimulation. In contrast, once antibody production to these same sites has been stimulated by the higher-affinity hog thyroglobulin determinants, the antibodies will bind to the cross-reactive sites on the rabbit protein.

So-called 'shared' determinants can be merely cross-reactive and certainly do not need to be identical. One might be able to distinguish between these categories if the antibodies are tested in assays where binding affinities are measurable (not in immunoabsorption where very low antibody affinities allow binding); in such conditions the appropriate differences in binding have been observed with several

families of protein antigens<sup>1–4</sup>, as well as with cytochrome *c*. With this last protein family, the data are clearly contrary to any generalization that antibodies reactive with self, elicited by foreign thyroglobulins, react mainly with shared antigenic determinants. Indeed, only one of 13 distinct, site-specific antibody populations isolated from sera of rabbits immunized against foreign cytochromes *c* was shown to bind to a region of the molecule where the host and immunizing proteins were identical<sup>5</sup>. This seems to be the result of a special cross-reaction situation.

With proteins having poorly defined or plastic conformations, a further problem is that amino acid sequence variations distant from a site where amino acid sequences are conserved may possibly change the conformation of that region from the protein of one species to that of another, thus making it antigenic. This is not the case with cytochrome *c* where it has been shown with several different antibody populations that amino acid sequence variations outside the antigenic determinant have no effect on the conformation of that determinant<sup>6–7</sup>. Moreover, the purification procedure in the case of thyroglobulin seems to change the molecular conformation to some degree<sup>8</sup>, and regions which should be antigenically silent on the basis of amino acid sequence could become immunogenic.

Furthermore, and perhaps most importantly, although our evidence<sup>9</sup> supports the thesis that evolutionary germ-line deletion of V genes coding for anti-self protein specificities can occur, one need not assume that all selective pressures affecting anti-self antibodies would be negative. Indeed, certain anti-self antibody specificities may be preserved if the antibody itself is important biologically, such as in regulation. Recent observations supporting this idea are that normal animals possess low levels of antibodies having specificities ranging from cellular antigens of the surface<sup>10</sup>, cytoplasm<sup>11</sup> and organelles (R. J., N. Klinman and E. M., unpublished results) to intermediates in metabolism<sup>12</sup>. Anti-idiotypic antibodies which are specific for self-immunoglobulin determinants seem to be involved in regulation of the immune system itself<sup>13</sup>. Certain anti-self antibodies could serve as a clearance mechanism for cell debris resulting from killing of, for example, virus-infected cells, or ageing and death in the normal cell cycle<sup>14</sup>. Depending on the nature of the self-antigen (structural lability, physiological location and biological role), the regulatory role of antibodies could vary. Therefore, not all self-antigens would be expected to express only the determinants in evolutionarily variable regions, as was observed with cytochrome *c*. However, immunization with cytochrome *c* has never led to any autoimmune pathology, in sharp contrast to what occurs with thy-

roglobulin and basic myelin protein. Thus, it would be surprising if the V genes corresponding to self-antigenic determinants in the latter two proteins were not as vigorously selected against as those for the former, unless there exists a biological mechanism of which we are unaware.

Finally, even if the V genes corresponding to the antigen studied were treated by the evolutionary process as seems to be the case for cytochrome *c*, one must take into account the appearance of the proteins on the evolutionary time scale relative to the appearance of the antibodies and their average rates of evolutionary change. More recently evolved self-antigens may not show complete antibody deletion of conserved region specificities as not enough time would have been allowed for selective pressures to take effect.

## Opiate receptors and adrenal medullary function

THERE is much interest in the role of enkephalins and opiates as transmitters or modulators of neuronal function. Costa and colleagues recently demonstrated<sup>1</sup> that high-affinity opiate receptors are present in the plasma membranes of adrenal chromaffin cells and proposed that "the activation of these receptors causes a non-competitive inhibition of catecholamine release elicited by the stimulation of nicotinic receptors." From

the data presented in their Table 1, it is apparent that morphine and several endogenous opioid peptides inhibit the nicotinic release of catecholamines from isolated chromaffin cells (approximate  $ID_{50}$ s: morphine,  $>10^{-4}$  M;  $\beta$ -endorphin,  $10^{-6}$  M; Met-enkephalin,  $>10^{-4}$  M).

We have performed similar experiments both on freshly isolated bovine chromaffin cells<sup>2</sup> and on the cells maintained as primary monolayer cultures<sup>3,4</sup> for up to 16 days. We agree with their findings on inhibition of catecholamine release by morphine ( $ID_{50}$   $1.6 \times 10^{-4}$  M),  $\beta$ -endorphin ( $5 \times 10^{-5}$  M), Met-enkephalin ( $5 \times 10^{-4}$  M) and Leu-enkephalin ( $>5 \times 10^{-4}$  M). Like Costa *et al.*, we found that the nicotine-evoked release but not the  $K^+$ -evoked release of catecholamines was inhibited by these compounds<sup>5</sup>. We also agree that the inhibition by these opiate compounds is noncompetitive with nicotinic agonists; however, we are not convinced by the specificity of the inhibitory effects of opioid compounds for the opiate receptor. In our hands, the two opiate antagonists naloxone ( $10^{-8}$ – $10^{-4}$  M) and naltrexone ( $10^{-8}$ – $10^{-4}$  M) did not reverse the inhibition produced by morphine, but rather they acted like morphine to inhibit the release of catecholamines (naloxone  $ID_{50}$ ,  $10^{-5}$  M; naltrexone,  $>10^{-4}$  M). Further, the effect of naloxone ( $10^{-6}$ – $10^{-4}$  M) and naltrexone ( $10^{-6}$ – $10^{-4}$  M) was additive to that of  $\beta$ -endorphin ( $5 \times 10^{-5}$  M) and morphine ( $10^{-4}$  M).

We were rather concerned that the levels of morphine and the endogenous opiates required to inhibit catecholamine secretion ( $10^{-3}$ – $10^{-5}$  M) were far in excess of the concentrations of these compounds required for effective receptor occupancy ( $10^{-8}$ – $10^{-9}$  M)<sup>1,6</sup>. In our search for compounds with higher potency, we found that levorphanol inhibited catecholamine release with an  $ID_{50}$  of  $4 \times 10^{-6}$  M. However, dextrorphan, the inactive enantiomer of levorphanol, was equipotent ( $ID_{50}$   $4 \times 10^{-6}$  M) in inhibiting the release of catecholamine from the chromaffin cells.

It is therefore unlikely that the receptor that is involved in these inhibitory actions of morphine and the endogenous opiates on catecholamine release is the same as that described in membrane preparations from the cells<sup>1</sup> and adrenal medullary homogenates<sup>6</sup> that is stereospecific and has high-affinity binding for Met-enkephalinamide ( $K_d$   $0.9 \times 10^{-9}$  M), naloxone ( $3.2 \times 10^{-9}$  M) and naltrexone ( $+Na^+$   $1.3 \times 10^{-9}$  M;  $-Na^+$   $3.93 \times 10^{-9}$  M).

Before any physiological role for opiates in the adrenal gland is considered it is necessary to demonstrate stereospecificity and reversal by antagonists. Although it is possible that slight differences in the way the cells are isolated and maintained in culture could account for the differences we observe, the basic question we raise here of the lack of stereospecificity and the

discrepancy between the levels required for receptor occupancy ( $10^{-9}$  M) and the biological effects ( $10^{-5}$ – $10^{-4}$  M) are still relevant and raise serious doubts about the proposed functional role of high-affinity opiate receptors in the modulation of catecholamine release from chromaffin cells.

COSTA ET AL. REPLY—Lemaire *et al.* have confirmed our report that opioids, when added to primary cultures of chromaffin cells, inhibit the release of catecholamines elicited by nicotinic receptor agonists. They pointed out that this inhibitory effect is nonspecific because the required dose of morphine is too high and the phenomenon lacks stereospecificity. Moreover, as the doses of naloxone required to reverse the action of morphine are also high, at these doses naltrexone acts as a partial agonist. Lemaire *et al.* failed to give significance to our finding that lower concentrations of naloxone are required to antagonize the inhibition of catecholamine release caused by  $\beta$ -endorphin. This peptide seems to have a greater affinity and a greater intrinsic activity with the opiate receptor of chromaffin cells which are operative in regulating the action of nicotinic receptor agonists on chromaffin cell stores of catecholamines. In conclusion, the data obtained by us and confirmed by Lemaire *et al.* show that this opiate receptor has peculiar properties (a low sensitivity to morphine, high sensitivity to  $\beta$ -endorphin). Moreover, as expected, the dose of naloxone required to antagonize the inhibition of catecholamine release elicited by opioids depends on the specificity of the agonist used.

These considerations are in line with current thinking suggesting that there are multiple forms of opiate receptors. Hence, it is not surprising that those located on

the membrane of the chromaffin cells have peculiar properties which must be studied before concluding that these receptors do not have a physiological role.

We studied the binding characteristics of the opiate recognition sites of chromaffin cell membranes and compared them with the recognition sites located in synaptic membranes prepared from frontal cortex of bovine brain. The opiate recognition sites of adrenal medulla have a high affinity, and a large capacity to bind etorphine and its structurally related antagonist, diprenorphine. This prompted us to study the action of both compounds on the nicotine-induced release of catecholamines. Diprenorphine, in concentrations of  $10^{-8}$ – $10^{-6}$  M, is devoid of any action, whereas etorphine prevents the action of nicotine with an  $IC_{50}$  of  $2 \times 10^{-7}$  M. The  $IC_{50}$  of diprenorphine to inhibit the action of an  $IC_{50}$  dose of etorphine is about  $3 \times 10^{-7}$  M. These results show a specific ability of etorphine to antagonize nicotine, and a great specificity of diprenorphine to antagonize etorphine.

We believe that the opiate peptides stored in the splanchnic nerve act on specific receptors located on the chromaffin cell membrane. When these peptides are released from the splanchnic nerve they may function as co-transmitters and modulate the number of receptors for acetylcholine that are available in the chromaffin cell membrane. According to this view, the receptor for the co-transmitter, when occupied by a specific agonist, can influence the number of acetylcholine recognition sites and the extent of the response to acetylcholine.

This type of synaptic regulation could be of interest in the development of new neuropharmacological agents that may modify synaptic transmission by acting on co-transmitter receptors. Theoretically, these potential drugs could minimize or maximize the response to primary transmitters without altering the frequency of neuronal activity, because they will not act on the receptor for the primary transmitter and obliterate the transmitter action. Probably, such drugs would not trigger as many side effects as those that block the primary transmitter receptor. The benzodiazepines are a good example of drugs that act on the co-transmitter regulation. By knowing the nature of various co-transmitters operative in different synapses, we might develop specific drugs that, similarly to the benzodiazepines, will modulate synaptic activity and be relatively devoid of untoward side effects.

## BOOK REVIEWS

## Time for thought

George E. Uhlenbeck

THIS book is a kind of essay about the age-old problem of the nature of time and especially about the question whether time "flows" or whether there is an arrow in time. Since these questions affect every human being, David Park has tried to reach both the general "time amateur" and the scientific expert — a considerable task. I think he has not quite succeeded, but as a result the style of the book is charmingly unpretentious and the author really does try to be clear.

The main line of the book is an attempt to elucidate the development of thought on the two kinds of time, physical time and time of human consciousness, which nowadays seem quite familiar, although they are still full of riddles. In ten short chapters the author traces the development from prehistoric times via the Greek philosophers and the Newtonian and post-Newtonian era to the most recent cosmological theories.

I liked especially the two early chapters entitled "The Greek Questions" and "The Newtonian Answer". The foreshadowing of the two times by Parmenides and Heraclitus, the speculations of Plato about these ideas and the discussion of the atomic theory introduced by Leucippus (perhaps to understand the causal direction in time) I found quite illuminating. The Newtonian chapter starts with a nice evocation of the wonders of the motions in the sky and then the author gives a concise but clear discussion of Newton's laws of dynamics and the law of gravitation. He scrutinizes especially the notion of absolute time, and tries to make clear that in Newtonian dynamics it is *not* necessary to think of a flow of time but that in fact the laws are time-reversible, as we would say nowadays. Here, he also touches on the special theory of relativity, the Einstein-Minkowski space-time concept, the Mach principle and the general theory of relativity. In the appendices he gives more details about these difficult subjects. I am afraid that for the general reader these appendices will be too technical, but they are a good reminder for the physicist, although Appendix 3 on the Mach principle is perhaps rather too speculative.

Now that Newton has clarified the

*The Image of Eternity: Roots of Time in the Physical World.* By David Park. Pp. 149. (University of Massachusetts Press: 1980.) \$14.50.

universal physical time, the question arises how to measure this time. This is of course done by a clock, but the author asks: What is a clock, and, especially, what is a good clock? He argues that a clock is a device whose law of motion is known, and the better this law is known, the better the clock is. Particularly he discusses the use of the rotation of the Earth from this point of view. This is all quite interesting, but I do have some qualms. Following Ernst Mach, I think that the question of what is a good clock is quite similar to the question of what is a good thermometer. In both cases the answer is essentially determined by convention. From the strictly operational point of view there is in my opinion no "true" time just as there is no "true" temperature.

Park devotes most of the rest of his book to the basic problem of the origin of the idea of the direction or "arrow" in time. If one accepts the Greek concept of the world as a huge collection of moving and interacting atoms, and if one believes that the Newtonian laws of dynamics describe these motions, how can one then reconcile the time-reversibility of these laws with the overwhelming common experience of the natural phenomena? We all know that we grow older and that we have to die. Further, a fundamental law of physics, the second law of thermodynamics, states that a closed system (as the world is supposed to be) tends to a state of equilibrium (or of maximum entropy) in which nothing further happens, the so-called *Wärme Tod*.

Early in this latter part of the book the author gives a short summary of the statistical interpretation of the second law. He illustrates it by a nice discussion of the so-called Maxwell Demon and of the little-known paper by Leo Szilard, which shows why the Demon is not able to violate the second law (in Appendix 1 a simplified but clear summary of Szilard's proof is presented.) Park also emphasizes the enormous length of the so-called Poincaré recurrence time for non-equilibrium states of macroscopic systems, and later argues that as a result these systems can be described causally in time producing our sense of past and future. Hence the arrow

of time on the macroscopic scale is guaranteed by the second law. Although this is certainly the generally accepted view, I feel qualms that the author's presentation now has its faults. I miss, for instance, a deeper discussion of the probabilistic aspects of the second law. No mention is made of the fluctuations around the macroscopic states which produce so many striking phenomena (such as the blue colour of the sky) and which limit the strict causality of the macroscopic laws of motion. But my main reservation is that the author does not make any distinction between living and non-living matter. He says (p. 54) that there is no doubt that our mortality is decreed in some way by the second law. He also does not mention the enormous amount of evidence for the existence of a biological evolution, which seems in such an apparent conflict with the second law. I think this is a serious omission.

The book goes on to tackle the cosmological time problem. After an instructive historical introduction about models of the Universe, the author discusses the modern cosmological "myth", the so-called canonical big bang theory. In my opinion this is the weakest part of the book. It is very speculative and I found it sometimes difficult to follow. The development of the Universe starting from the big bang clearly defines an arrow in time, and I think the author tries to reconcile this with the arrow of time of the second law of thermodynamics. Apparently his arguments have not yet been published in detail. They depend on the notion of microscopic order, which quite escapes me. He touches on the question of a possible end of time for oscillating models of the Universe, and also discusses the possible cosmological significance of the large dimensionless numbers occurring in the present theories.

The last chapter has the charmingly modest title: "Can We Finally Say Anything Sensible?". It is a summary of the basic theme of the book, the existence of two kinds of time, the physical time as measured by clocks and the time of human consciousness which is marked by events. Is there a relation between the two? The author notes that this profound question, which goes back to Plato, is clearly related to the great dilemma between the apparent causality of all natural phenomena and our obvious sense of free will. He makes the

interesting suggestion that perhaps the two times are a pair of concepts which are — like the pair of concepts, free will and determinism — complementary in the sense of Bohr. They are two aspects of human knowledge which are both required for our understanding of the world but which exclude each other. Park hopes that this view will lead to a unification of the two times on a higher abstract level. I am

sceptical, mainly because of my qualm about the neglect of the life sciences. To understand time 2 one surely should know what life is!

In all, I think that this is a stimulating book and I gladly recommend it. Each reader will undoubtedly have several objections as I had, but there is also no doubt that the book will make him think again about the roots of time. □

## Inheritance: the immunological challenge

N.A. Mitchison

*Somatic Selection and Adaptive Evolution: On the Inheritance of Acquired Characters.* By E. J. Steele. Pp.92. (Williams and Wallace: Toronto/Croom Helm: London, 1980.) \$14.95, £8.95.

THIS rather thin little book advocates the inheritance of acquired characteristics. Its interest lies in the opportunity it offers of observing how a competent young cellular immunologist came to hold such a view, and in the papers published earlier this year by the author, jointly with R. Gerczynski of Toronto, claiming to establish the validity of such inheritance in respect of immunological reactivity. Whether this idea need be considered seriously is a matter of opinion. R. B. Taylor (*Nature* 286, 837; 1980) does so. I do not, on the grounds that such an implausible claim need not be taken seriously to start with except by extreme specialists, in the sense of those willing and able to attempt to repeat the work. Otherwise, let time be the test: if Steele and Gerczynski can make something of their story — pursuing its implications and mechanisms — then let them do so. The rest of us can afford to wait and see. Fortunately, Steele shares the view that their work will stand or fall by what he can accomplish in a follow-up. For example, can heightened as well as diminished reactivity be transmitted by males to their offspring? Can genetically tolerant (heterozygous at H-2) as well as experimentally tolerant males transmit?

The idea is that retroviruses transmit genes from one cell to another by picking up messenger RNA, an old speculation of Temin's. To this is added the thought that the hypothetical flow of genes will favour those genes expressed in clonally expanded cells. As ideas there is nothing wrong with these, except that they are a little old hat now that DNA transfection has become an established technique — which can be used, as M. J. Cline has shown, to transmit methotrexate resistance genes from one mouse to another. The question is whether gene transfer between cells occurs naturally on any appreciable scale. The stability of Mendelian segregation ratios argues that it

does not, particularly when account is taken of segregation from a parent carrying a non-functional allele and from females with X-chromosome inactivation. Steele does not try to rebut or even evaluate this evidence. Instead he quotes a handful of apparent exceptions. Of course, apparent exceptions will turn up if one looks hard enough, but as exceptions they surely deserve critical examination. This they do not receive here.

For instance, Steele cites the apparent transmission of "individual-specific" antibody idiomorph from immunized rabbits to their offspring. But interpreting these data is tricky, because the assignment of idiotypes to the "individual-specific" as distinct from the "germline-encoded" category is doubtful. Furthermore, when a female is immunized before giving birth, as was the case for the data showing apparent transmission, there is a possibility that passively transmitted antibody may have favoured production of the idiomorph in the offspring. Or to take another instance, Steele cites the apparent production of sickle-cell haemoglobin trait offspring from normal parents as evidence of gene transfer. What is critical here is whether the parents were correctly typed, and to the extent that the typing is more rigorous (that is detects smaller amounts of HbS-type haemoglobin) the argument for gene transfer is weakened. These are technical points, but they indicate the incomplete nature of Steele's argument.

Much the same applies to the musings on the history and future of Lamarckian ideas. A scholarly discussion of these topics would require a coverage of nineteenth-century intellectual history and twentieth-century population genetics which is not the aim here. It is particularly disappointing to find no mention of the problem of conserving genetic variation under any scheme such as that proposed.

If Steele's work can be repeated, and if his interpretation stands, here is one colleague who will most humbly eat his words. □

N.A. Mitchison is Professor of Zoology at University College London.

## B, Cu, Co, Fe, Mn, Mo, Zn . . .

T.S. West

*Applied Soil Trace Elements.* Edited by Brian E. Davies. Pp.482. (Wiley: 1980.) £22.50, \$67.50.

PROBLEMS associated with contamination of the environment by traces of heavy metals are of considerable concern to many scientists and laymen. Somewhat strangely, relatively little interest is shown in the equally important problems associated with deficiencies of the trace elements that are essential to all forms of life. Elements such as boron, copper, cobalt, iron, manganese, molybdenum and zinc act as essential catalytic components in most enzyme systems in plants and, boron excepted, in animals where many other elements are vital to the considerably more complex biochemical processes involved.

All trace elements in biological systems are derived from the Earth's crustal rocks originally, but come mainly via weathering of the primary minerals of the parent rocks in soils through plants and, to a lesser extent, through the water supply. This somewhat curiously titled book is a synthesis of most of our knowledge of the trace elements that are known, at the present time, to be "biosignificant". Written by agronomists, chemists and geologists, it is an excellent account which can be recommended to all who are directly concerned with these matters, to others who work in associated areas in the medical sciences and indeed to all who are scientifically aware. It is well written and in many places quite fascinating.

I would have preferred to have seen a fuller account of the chemistry, particularly chemical speciation, of these elements in the soil, and a more systematic consideration of the demands made by plants on the soil. This could have been done at the expense of the rather over-detailed account given of analytical procedures, although one of course does recognize that virtually all present trace-element work in soils is heavily dependent on advances in the analytical sciences.

However, there is no doubt that this book is a major contribution to the subject and in my opinion it is one of the most important to have been published. It is well written and illustrated, and handsomely produced. One hopes that the editor will keep the team together to produce a second edition, when many of the exciting developments that are now taking place — particularly in speciation and synergism between elements — could be given as well as an account of the "new" elements.

This book deserves to be widely read and it probably will. □

T.S. West is Director of the Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen.

# Anthropology and ecology of the world's savannas

Peter D. Moore

*Human Ecology in Savanna Environments*. Edited by David R. Harris. Pp.522. (Academic: 1980.) £21.50, \$49.50.

THERE is a romantic appeal about certain of the world's biomes which defies scientific explanation. What is there about desert, rain forest and tundra which excites the imagination, and why does the savanna lack the same magic? It was a similar concern which led David Harris to co-ordinate the Wenner-Gren Foundation conference in 1976 which formed the basis for this book. The general lack of public, and perhaps even scientific, interest in the savanna regions is all the more surprising when one considers the close association of early Man with these tropical grasslands, together with the modern problems of pastoral societies in these regions and the growing conflict with wildlife conservation.

The book is divided into three parts. The first deals with the occupation and exploitation of savanna environments since early prehistoric times. J. Desmond Clark attempts a synthesis of the pollen and vegetation data of Van Zinderen Bakker with the rapidly accumulating information concerning prehistoric communities in Africa. Man, he claims, remained restricted to the open savanna environments until about one million years ago, when *Homo erectus* first invaded the Ethiopian highlands. Hammond provides a similar synthesis for Central and South America, although the palaeoecological data is very much thinner. Within this section of the book also fall a number of anthropological studies of tropical Australia, Africa, India and South-east Asia. To an ecologist, some of the uses of ecological terms in an anthropological context may seem a little misplaced; is it reasonable, for example, to say that pastoral behaviour in East Africa shows the elements of an r-strategy? The statement is largely based upon the process of local resource exhaustion, followed by a moving on to new grazing land. The MacArthur and Wilson model is becoming unrecognizable.

Overall, one is left with the impression, from this first part of the book, that anthropologists have now gathered much field data from their respective study sites and are searching avidly for generalized models.

In the second part of the book, the emphasis moves from savanna history and exploitation systems, to present ecology and management. Here some authors use the ecosystem approach and one is supplied with data concerning production rates and nutrient distributions, particularly in relation to human land use. Among these papers that of P. A. Jewell, concerning the management of game and domestic livestock in African savanna, is outstanding,

East African savanna: Grant's gazelle grazing in the Serengeti.

both in the clarity of its presentation and in the wealth of carefully chosen data it contains. Beside it, the paucity of information from other areas is apparent.

The final part of the book concerns the human biology of savanna peoples. This contains largely physiological, nutritional and epidemiological information concerning the savanna populations, which is vital for an understanding of the ecology of Man in these areas.

One can always think of other subjects which could have been included to make any book more comprehensive in its coverage. High on my list here would be a

contribution by a palaeoecologist, who could put into perspective the limitations of the pollen data, to which so many of the authors refer. Also, a chapter concerning the ecology and importance of fire in savanna would have been helpful. But one must draw the line somewhere, and this book contains more than enough to whet one's appetite and enthusiasm for that neglected biome where Man himself has his roots. □

Peter D. Moore is Senior Lecturer in the Department of Plant Sciences, King's College, London.

## Slime mould jubilee

G. Turnock

*Growth and Differentiation in Physarum polycephalum*. Edited by W. F. Dove and H. P. Rusch. Pp.250. (Princeton University Press: 1980.) £13.70, \$25.

THE true slime mould, *Physarum polycephalum*, has a respected position in the catalogue of lower eukaryotes used for studies of cell biology in general and of differentiation in particular. Two features of its complex life cycle are of especial interest: first, the high degree of synchrony that is characteristic of nuclear division in the coenocytic plasmodium, and, second, the dramatic degree of differentiation involved in the transition from amoebae, which grow and divide as single cells, to plasmodia, which grow without any further cell division. Thus the amoebal-plasmodial transition is a link between two vegetative growth phases; it provides a refreshing contrast for the study of differentiation by comparison with

formation of spores or resting stages — not that *Physarum* cannot supply these as well.

One person, H. P. Rusch, played a particularly important role in stimulating biochemical studies of *Physarum*, and this book celebrates the silver jubilee of the work begun by his group at the McArdle Laboratory at the University of Wisconsin. Cancer research is the remit of the McArdle Laboratory and Rusch chose *Physarum* as a model organism for the basic analysis of growth and differentiation, although he admits in the Introduction that his work on carcinogens was becoming hampered by

James Six

*The Construction and Use of a Thermometer* by James Six, reviewed in the Autumn Books Supplement of *Nature* (288, 36; 1980), is available from Nimbus Books, 84 Sydney Road, London N10 2RN, price £15 + 60p post and packing.

the development of an allergy to rodents.

With Rusch as one of the co-editors, several of his former collaborators and others have contributed a series of essays describing the progress achieved in the study of *Physarum*. The collection will be of value to all who work with the organism and to others who wish to learn about its peculiarities for the first time.

The potential of genetic studies is emphasized in several of the articles, and the defined strains now available make possible, for example, the biochemical analysis of mutants defective in their ability to undergo the amoebal-plasmodial transition. Heat-sensitive mutants have

been isolated in several laboratories and there is optimism that this class will contribute to our understanding of the control of the synchronous nuclear division cycle in the plasmodial phase. Here, the major challenge, as Holt points out in the first article, is to relate the coordinated replication of the genome to the control of nuclear division.

It is a tribute to the interest that Rusch was able to stimulate that most areas of research on *Physarum* can be covered by his former associates. Transcription, the nuclear replication cycle, genetics and details of the different developmental phases are amongst the topics described.

Throughout there is a discussion of possible areas of progress, although some of the suggestions have a slightly frenetic ring, more appropriate to a grant application than to a collection of critical essays. Another minor criticism is the overlap in details provided in the different chapters. This could have been avoided by stringent editorial control; on the other hand, the argument for repetition is that it does enable each essay to be read individually, and the book as a whole can certainly be recommended. □

G. Turnock is a Senior Lecturer in Biochemistry at the University of Leicester.

## All you wanted to know about inflammation

J. L. Gordon

*The Cell Biology of Inflammation. Handbook of Inflammation, Vol. 2.* Edited by Gerald Weissman. Pp.714. (Elsevier/North-Holland Biomedical: 1980.) Dfl. 230, \$112.25.

THE topics embraced by the title *Cell Biology of Inflammation* cover a fair proportion of many lecture courses in pre-clinical pathology and also touch on several aspects of fundamental research into cell biology — including cell maturation, adhesion, locomotion, phagocytosis, secretion and intercellular interactions —

as well as tissue catabolism, remodelling and repair. Any editor attempting to assemble a book under this catch-all title is faced with a daunting task.

The first point to make, therefore, is that this book succeeds unusually well — better than any other single volume I have read. Several of the authors are acknowledged leaders in their field, and the overall quality is high, with some of the chapters being quite outstanding. I particularly liked Dee Bainton's general view of "The Cells of Inflammation", and there are two excellent contributions on mononuclear

phagocytes from Edelson and from Egal and Davies.

It is impossible to do justice to all the book's 18 chapters in a brief review; the topics cover an astonishingly wide range, from "template activity of isolated lymphocyte nuclei in priming exogenous bacterial RNA polymerase" through "eosinopoiesis and mast cell desensitisation" to "the ultrastructure of pre-lymphatics and tissue channels that constitute the sol phase of interstitial tissue". However, although the coverage is eclectic, this book is not a collection of esoterica — the balance is good and the tone is authoritative, inasmuch as it can be with a subject such as this where so much still remains to be learned.

There are, of course, some disappointments: for example, the reviews of the fast-moving areas of research are already dated, because most of the literature surveys seem to have stopped at the beginning of 1978, and some even earlier. Also, there is inevitable overlap with some parts of Vol. 1 in this series (*Chemical Messengers of the Inflammatory Process*), but this is a much better book than its predecessor — so much so that one wonders what remains for future volumes in this series. The standard of production is high and the copy is clean — Graham Lewis's criticism of the proof-reading of Vol. 1 (*Nature* 286, 89; 1980) perhaps had a salutary effect.

In summary, this is a substantial and important volume, and it deserves to be widely read; it left me with the impression that it could have been subtitled "all you wanted to know about inflammation but were afraid to look for in the original literature". It provides a valuable source of information and reference for those already working on some aspect of the cell biology of inflammation, and it may also stimulate those working on other topics to enter this fascinating field. □

J. L. Gordon is a Principal Scientific Officer in the Department of Cell Biology, ARC Institute of Animal Physiology, Cambridge.

## Until winning isn't everything, the public is damned.

Nuclear waste v. cheap energy; the DC-10 disaster v. air travel; genetic engineering v. reducing birth defects. Complex socio-scientific issues like these cannot be adequately addressed by our "either/or" system of dispute resolution, asserts legal scholar Milton R. Wessel. How to truly serve the public interest—by replacing winner-take-all adversary law with "the rule of reason"—is spelled out in *SCIENCE AND CONSCIENCE*, a work that every concerned citizen should read.

# London medical schools stay in limbo

The University of London is making heavy weather of its attempts to reorganize its pattern of medical education. For most of the past year, the university but especially the medical schools which are constituent parts of it have been engaged in a fierce and frequently public argument about the proposals for rationalization put forward in February by a committee under Lord Flowers. Normally staid academics and, even more surprising, college principals with their origins in the civil service, have been writing to the newspapers, making public speeches and behaving as if this or that recommendation could be implemented only over their dead bodies. In one respect, at least, the volume (and the manner) of the protest has been effective. For the time being, nothing will be done. At its last meeting, the court of the university decided to postpone a decision until its next meeting, in February. This was a consequence of the decision of the senate of the university on 29 October (see *Nature*, 6 November) that no part of the proposed reorganization should be implemented without the consent of the medical schools concerned. So the hapless planning committees of the university are once more in session, seeking a formula that will win the consent of legally autonomous and temperamentally unruly medical schools to a measure of central government which is at once unpalatable and unfamiliar. If the issue is again postponed in February, the university will be running true to form. In the process, the foundations of its medical education will be further eroded.

Delay is of course a familiar response of academic institutions to the need for decision. The University of London has been grappling with problems of medical education since 1966, when the report of the Royal Commission on Medical Education, recognizing that the university is the chief source of qualified physicians in the United Kingdom, made specific proposals for reorganization. Since then, nothing much has happened, although the need that something should have become more urgent. The continuing decline of the population of London has reduced the numbers of patients to whom medical students in London have access; the National Health Service has embarked on a policy of redistributing hospitals and other medical services in accordance with these demographic trends and is now faced with a more permanent decision about the provision of hospital beds in London (brought about by the need either to replace old hospitals or to close them down). Although five among the twelve medical schools have been rehoused during this long period, resources available for teaching have steadily declined. Since 1973, the university has been trying to follow the advice of the University Grants Committee that more funds should be channelled to the medical schools. Its admission of failure provoked the Flowers inquiry. Things can only get worse while the university broods about its response. Given the importance of the university's medical schools in the pattern of medical education in the United Kingdom as a whole, the consequences of delay are not merely parochial. All medical schools will be affected.

The essential ingredient of the reorganizations proposed by the Royal Commission in 1966 and the Flowers committee in 1980 is the shotgun marriage. The Royal Commission had the twelve medical schools marrying off in pairs. In the event, one of these marriages was partly consummated in the relationship which has grown up between the London Hospital and St Bartholomew's Hospital (or, more accurately, the corresponding medical colleges). The other prescribed partners have fallen back jealously on their habitual celibacy, to which they have a legal right which they can surrender only voluntarily. The Flowers recommen-

dations took a similar form, but were inevitably more specific. Some marriages were to be arranged, two pre-clinical schools (at King's College and Westminster Hospital) were to be abandoned and the twelve postgraduate institutes within the university were either to be merged with teaching hospitals or to be relocated (in premises vacated by Middlesex Hospital). The Joint Planning Committee set up by the university senate and court acknowledges that the putative partners are within their rights when they insist that they would prefer to remain as they are. The university could nevertheless force change upon them by robbing them of funds — or by telling the National Health Service what future it sees for them. The effect of the senate's decision is that the pre-clinical schools at King's College and Westminster Hospital should be closed (and the clinical school at the latter merged with that at Charing Cross).

The university's dilemma is thus familiar to all those who work in universities in the process of change. Should a university administration force reorganization on unwilling academics? Should it, by failing to decide on a course of action, at the same time connive at a further deterioration in the quality of education? Or should it go all out for a decision in February, and if so which of the several canvassed options should it be? The greatest danger now is that the university will find itself plumping for one and sticking with it, come what may.

In reality, none of the schemes that have been advocated is ideal, although many of them contain common elements of agreed good sense. The shotgun marriages which have been proposed would often result in widely scattered groups of buildings united only by the new (and synthetic) names on their letterheads. What the university now needs is not a once and for all solution but a less ambitious and more persuasive programme of immediate action and a framework of management within which a more economical pattern of medical education can evolve, and be made to evolve, in the course of, say, a decade.

In the short run, there are administrative steps that should be taken — the rump of the Royal Free Hospital School of Medicine should, for example, be decanted from its old building, allowing the site to be sold. Similarly, the weaker among the postgraduate medical institutes — at a guess, six out of the twelve — should be looked at critically and perhaps even deprived of their academic pretensions. (Many of them would still have a useful service role within the National Health Service.) For the longer term, however, the university should be prepared to settle for a mechanism, not a prescription. And if the National Health Service demands some simple plan, it must be told that if the London medical schools are such an important part of British medical education, it is folly that their quality should be jeopardized by too hasty a solution.

In any case, the collective brooding about the future of the London medical schools has surprisingly left entirely out of account the paramount consideration — the character of the medical education the schools at present provide. The Flowers committee had some telling points to make about the way in which several of the existing schools are so short of resources that they cannot employ the full range of the academic staffs they need, but otherwise raised only the arid issue of whether it is better, within the peculiar pattern of British medical education, that intending physicians should be taken straight from secondary school and plunged into a hospital environment ('vertical integration') or, alternatively, allowed to spend their three pre-clinical years in a more normal type of college (the 'multi-faculty' approach).

Nobody has seriously considered whether some quite different pattern, perhaps the American pattern, might be preferable, at least in some of the London medical schools. No serious consideration has been given by the university (as distinct from individual medical teachers or schools) to the pattern of the medical curriculum. The relationship between postgraduate education and postgraduate research is almost entirely unexplored. So is it not high time that the university that happens to be the most prolific source of physicians in the United Kingdom should ask for a stay of execution while these difficult but important issues are hammered out?

The obvious difficulty is that, as on many previous occasions, the medical schools and even the university would use delay as an opportunity for doing nothing. What can make them change their ways? One good sign is that the troubles of the past few months have given all concerned a nasty shock, which they will not quickly forget. But there are also obvious combinations of stick and carrot that could persuade the medical schools that it is in their common interest to find out what changed pattern would best suit the long-term needs of medical education. One present absurdity is that the twelve medical schools, nominally constituent parts of the same university, appear to be even more concerned with their independence than with the education of their students. The university has a committee to scrutinize

developments by the separate schools, but the joint planning board says it would be impossible for that body to arbitrate between the existing medical schools on questions such as which should do what.

Why ever not? Membership of even the loose federation called the University of London surely entails some sacrifice in a common cause. They should be willing, and if not should be compelled, to sacrifice some of their autonomy. The only basis on which they can continue to resist recurrent proposals of shotgun marriage is that they should be willing to join in a still more ambitious venture, one intended to weld the London medical schools into a single coherent complex of institutions concerned with the training of doctors. Whatever the separate schools now pretend, many of them are too weak to stand indefinitely on their own feet. Too many academic departments are too small to be viable. What the schools need is a system in which the university as a whole provides certain common academic services which are beyond their separate resources. Then they might have the best of both worlds — diversity of style but effectiveness (and efficiency) in their teaching. As things are, they invite only the further erosion of their resources, the continued impairment of the quality of their teaching and the loss of such sympathy as they retain from those who share the schools' own distrust of coercion in the administration of universities.

## Best not to attend on Mr Moon

Next to Pope John Paul II and, possibly, the Reverend Ian Paisley, the internationally best-known religious leader is probably the Korean Sun Myung Moon, the founder of the organization called the Unification Church. In the past few years, the church has been constantly in hot water throughout the world, defending itself against complaints that in recruiting members to its ranks it frequently exerts undue influence on people who are temperamentally far from robust. The Unification Church is less well known (through its subsidiary organization, the International Cultural Foundation) as a sponsor of scientific conferences. The ninth "International Conference on the Unity of the Sciences" is now under way in Miami Beach (27–30 November), with the theme "Absolute values and the search for the peace of mankind". The chairman is the distinguished scholar Morton A. Kaplan from the University of Chicago. The vice-chairmen include Dr Frederick Seitz, most recently president of the Rockefeller University, and Dr J. S. von Euler, professor of medicine at the Karolinska Institute in Stockholm. This conference is as well blessed with distinction at the top as anybody can ask. The same, for what it is worth, is true of earlier conferences in the series — last time, for example, the chairman was Professor Eugene Wigner of Princeton. With such credentials, why should the question repeatedly be asked why people keep turning up?

The question is a controversial one. Those who participate in these conferences are usually at pains to emphasize that they have found them valuable, even stimulating. The same people are usually willing to keep on going back. The case for doing so was well put by Professor Nicholas Kurti two years ago, on the eve of the seventh conference held in Boston (see *Nature* 276, 206; 1978). The broadness of the themes of the conferences (in 1978 the subject was "the re-evaluation of existing values and the search for absolute values") does not always lead to the confusion that might be expected. Professor Kurti has said (and others have echoed him) that he has on the contrary found it useful to be required to think and talk about subjects that do not ordinarily come his way. Professor Kurti in his article made no secret of his view of the Unification Church ("many distasteful aspects") and of what he thinks of Mr Moon (not much), but he stoutly affirmed that the Unification Church could have derived no substantial propaganda value from the proceedings of the conferences, and that in any case no continuing obligation to the Unification Church would be incurred by accepting Mr Moon's hospitality (which is generous, to say the least). There is no reason to dispute

those opinions. It does not, unfortunately, follow that attendance is without consequence.

Quite apart from the source of their sponsorship, the conferences have some curiously shabby attributes. Perhaps the most serious complaint against them is that they are not so much sponsored as made possible by patronage. A part of the price paid by the assembly is that Mr Moon himself may choose to deliver an address of such vacuity that its thesis would not survive for ten minutes in an undergraduate seminar. By all accounts, however, Mr Moon's ideas survive more or less unscathed the gathering of Nobel prizewinners and other distinguished people who are required to listen to them. It is unseemly that scholars, but especially distinguished scholars, should behave in such a way. It is also unseemly that people should participate in conferences in which the participants, however individually distinguished, cannot collectively boast that they are the group ideally suited for the discussion of the broad themes with which they are faced. (To judge from the Miami Beach programme, some of the committee meetings, on the other hand, should be rewarding.)

Above all, it is unseemly that serious people should turn up at meetings where every other session title includes the word "values", where the title of the conference as a whole includes the phrase "absolute values" and where there is no means of knowing what these terms mean. It is true that participants are not required to assent to the "chairmen's affirmations" (read by Sir John Eccles to the fifth conference in 1976) that "scholars and scientists throughout the world should endeavour to search for absolute values and harmony among the sciences". Mr Moon might, however, get better value for his money if he required participants in advance to write a brief note of what they understand by these high-sounding words. As things are, participants are allowed to write on a subject of their own choice, receiving \$200 if the manuscript is sent in before 1 September and a further \$300 when what they write is "approved" for publication.

The case against these conferences, then, is self-contained. Professor Kurti may have been right two years ago to assert that participation does not necessarily give comfort (or much comfort) to the Unification Church, but the conferences themselves appear not to be as distinguished as those who participate in them, and should therefore be encouraged to wither away. For it is bad for the reputation of scholarship, dedicated as it is to the pursuit of excellence, that it should be seen to lend its name to extraneous causes. It matters less that they are those of the Unification Church than that they are second-rate.

# Harvard finally backs off gene venture

## Anxiety about conflict of interest wins

Harvard University's flirtation with the commercial exploitation of recombinant DNA research came to an end last week. After a period of agonizing and second thoughts by the faculty and administration (see *Nature* 20 November), the president of the university, Dr Derek Bok, put out a statement that the university would not after all participate in a company to exploit the work of Professor Mark Ptashne's laboratory.

What seems to have persuaded the university not to go ahead were the arguments of faculty members that a direct commercial interest by Harvard in the exploitation of ideas generated by one of its professors would create intolerable conflicts of interest. One argument was that the university would have found itself favouring the academics working for the commercial company in routine academic matters such as the appointment of staff, the allocation of laboratory space and even the provision of research funds.

It seems that the university administration has accepted these arguments only reluctantly. Mr Daniel Steiner, the university's Chief Counsel, said earlier this week that the university had approached Professor Ptashne as long ago as last February, suggesting the formation of a commercial company to exploit some of the research on which he was then engaged. It seems that until the faculty meeting in October, the university administration had not anticipated the strength of the reaction by some academics.

Other members of the faculty complain that the university administration was naive in its expectations of the commercial exploitation of recombinant DNA research. Under the proposed arrangements, the new company to be set up would have been financed by venture capital from commercial sources, would have had its own premises and its own managers and would not have been connected with Harvard by name. The university would have been given between 10 and 15 per cent of the equity without direct investment and there was also to have been a royalty on sales at a level not fixed.

In return, the university would have licensed the new company to use such patents as emerged only from Professor Ptashne's laboratory. Critics point out that the university would nevertheless have been a serious shareholder in the new company and that it could not have avoided committing resources of its own if,

for example, the new company ran into trouble.

Whether a commercial company based on Professor Ptashne's work will now be set up (without a shareholding by the university) remains to be seen. Professor Ptashne is thought to have been working since February this year, with the help of Professor T. Kanaguchi, on a novel method of making fibroblast interferon by cloning the gene at a more efficient expressing site in a plasmid in *Escherichia coli*. It is thought that the university has already committed some funds to this research.

Harvard's interest in the exploitation of patents arising from academic research dates back to 1975, when the university took advantage of a change in rules on patent law promulgated by the National Institutes of Health, and set up an office to encourage the patenting of inventions and the assignment of rights to the university.

Within the Harvard faculty, opinions remain divided. Some erstwhile supporters of the proposal regret the collapse of the administration's plan and hope that, in the

months ahead, less formal and perhaps more profitable ways of making progress may be possible.

Opponents, however, include some who argue that conflicts of interest are unavoidable if the university is to have a commercial interest in the exploitation of one professor's academic research. One irony that has emerged is that the university has indirectly acquired an interest in the recombinant DNA company Biogen, of which one of its professors, Dr W. A. Gilbert, is a prominent member. This interest has arisen independently, through a commercial investment in a venture capital company and in the normal process of university investment.

Among the critics, there are some who would use the events of the past few months as an occasion for a more general inquiry into the propriety of external entrepreneurial activities by any members of the faculty. One such critic said, earlier in the week, that Harvard was nevertheless comparatively "clean" — "You ought to look into what happens at MIT, down the river".

## JET fusion experiment seeks growth

The case for making Europe's big fusion experiment, the joint European torus (JET), bigger and better — and twice as expensive — is now being argued by physicists connected with the project. They are arguing that the machine, now being built at Culham in Britain, should be equipped to allow full thermonuclear experiments using deuterium-tritium mixtures.

This proposal for "extended performance" is being discussed by the JET Council, the governing body for the project. It could be presented to energy ministers of the European Community in mid-1981, when the community's five-year fusion research programme is due for reappraisal.

"Extended performance" to reach ignition conditions was envisaged in the original JET design (completed in 1975) but was thought at the time to be financially too risky, for theorists had predicted that new high-temperature instabilities might set in before the plasma ignited. Since then, experiments in existing devices have led to much greater optimism. In particular, an experiment in the Princeton tokamak is taken to indicate that the feared instabilities do not exist.

This development makes the basic JET now look rather tame, and suggests that it should be possible to aim quite quickly at deuterium-tritium experiments. But this requires a greater power supply to increase the toroidal field power by 50 per cent and the heating power by 150 per cent, new diagnostic devices, remote handling

equipment and a degree of radiation protection (from neutrons emitted by the ignited plasma). There will also have to be facilities for storing and handling tritium (itself an expensive commodity).

The latest estimate for the cost of basic JET is 263 million European Units of Account (EUA) (£147 million), a figure largely explained by inflation since the original amount fixed in 1977 (185 million EUA). The cost of the extensions now proposed is not yet fixed, but is likely to double that amount.

Meanwhile, JET construction is going well, though building delays have made the mid-1983 physics target look tight. Twenty of the 36 toroidal coils have been delivered and tested successfully; and buildings are now either complete and occupied or well under way. The vacuum vessel is a little late — the first octant was due in October but is not now expected until January — but it is hoped to make up the time lost. Staffing is up to target: 300 out of 320 appointed.

Contracts have now been placed for almost all the major items for the basic machine but it will be necessary to place contracts soon for the sophisticated equipment needed for the extended version if the momentum is to be maintained. Under this programme, JET will be commissioned early in 1983, and will begin physics proper in the summer of that year. There would be two years of experiments with hydrogen, investigating scale effects, a year with deuterium, and then, if everything went smoothly, work with a deuterium-tritium mixture in late 1986. It

is not known how long JET could work with a radioactive plasma, until its materials become too active to handle efficiently.

The Princeton tokamak fusion test reactor (TFTR), which is of similar scale to JET, is already being installed in its buildings. According to JET officials, the TFTR will be running some six months before JET itself.

Robert Walgate

## Telecommunications

### Monopoly in doubt

Sir Keith Joseph, allegedly the British Cabinet's hard man on monetarism and other issues of grand policy, last week published a soft, even muddled, bill for the reorganization of the nationalized British telecommunications industry. The bill, which the government hopes will be law before the end of this session of parliament, would split the nationalized British Post Office into two parts, one (called the Post Office) concerned with mail and the other (British Telecommunications) with the development and operation of the telecommunications network.

The bill confirms British Telecommunications in its monopoly of the telecommunications services in Britain including — a minor surprise — the right to maintain all equipment connected to the network. But the bill provides for "approved" equipment to be attached to the network, for private organizations to use the network for selling what are called "value-added services" and even for letting the Secretary of State license private telecommunications networks if he thinks fit.

Although these developments were foreshadowed in Sir Keith Joseph's policy statement last July, the extent to which the bill leaves final decisions about the shading of the monopoly in the hands of the Department of Industry is surprising. Instead of attempting to define what technical criteria should be satisfied by privately supplied terminal equipment, for example, the bill gives the Secretary of State power to arrange for an approval procedure. Questions of when outsiders would be allowed to lease the telecommunications network (and at what cost) are being looked into by Professor Michael Beesley, but again it will be the Secretary of State who will decide what should be permitted.

British Telecommunications (which will not formally exist until the bill is law) is plainly unhappy with the extent to which the bill would give the Department of Industry a crucial and perhaps arbitrary say in its future business. Sir Keith's dilemma seems to be that, having shrunk from going the whole hog and defining British Telecommunications as a common carrier, he has had to fall back on ministerial direction as a way of nudging the corporation in his preferred direction.

The bill may thus be a recipe for constant wrangling between the communications network and the civil service (which, paradoxically, has been much involved with the affairs of all nationalized industries since the election of May 1979).

The new regime at British Telecommunications also promises continued uncertainty about the financing of the telecommunications network. The new corporation will be encouraged by the bill to set up new subsidiaries to compete with private manufacturers of terminal equipment, but will be required to finance these developments within the tight restrictions at present applied — and which, in effect, imply that most of the capital cost of renewing the British telecommunications network is paid for by current users of the network.

Last week, Sir Keith Joseph offered no escape from this corset except to the extent that British Telecommunications may be able to set up joint ventures with private industry which are financed privately and not under the corporation's financial control. Delphically, he declined last week to say what sorts of ventures he was thinking of, thus lending credence to the view at British Telecommunications that the proposed device will offer very little escape from the present squeeze.

Despite reports to the contrary, there appears to be no threat of interference with the programme of telecommunications research and development, based at the laboratories at Martlesham Heath in Suffolk. The government intends this bill to be law within a year. Its plan to sell off Cable and Wireless is the most likely snag.

## Malaysian education

### Pressures ease

#### Kuala Lumpur

Faced with internal racial pressures and a growing concern about academic quality, educational authorities in Malaya seem to be easing up slightly on the harshness of previous measures to reform the country's education system.

Two aspects of this policy have come under particular criticism. The first, known as restructuring, is the preference that has been given to Malay students and staff over those from Malaya's other two major ethnic groups, the Chinese and the Indians. The second, nationalization, has been the requirement that all school and university courses should eventually be taught in Malay rather than in English, both initially used as official languages after the country's independence from colonial rule in 1957.

Both goals are part of a new economic policy introduced by the Malay government in 1971. This followed widespread racial riots sparked off by Malay fears that their post-colonial political dominance was about to be challenged by the economically more powerful Chinese, who had voted

strongly for the main opposition party in the 1969 elections.

One result of the subsequent "reforms" is that, from 1985, all university courses will have to be taught in Malay, the culmination of a process which started in 1976 with the requirement that Malay be the language taught in primary schools, and which has been climbing the educational ladder one year at a time ever since.

The policy has been effective in increasing an awareness and use of Malay, now the official language in which all communications with civil servants, for example, must be carried out. But many university teachers now argue that an excessive concentration on Malay is already placing students at a disadvantage, particularly in science subjects where most textbooks and almost all scientific journals are written in English, and many scientific concepts have no Malay counterpart.

Partly in response to this criticism, the government is now boosting the teaching of English as a second language in Malaysian schools, arguing, for example, that English is necessary for graduates entering technical employment or intending to pursue postgraduate studies abroad.

A recent decline in the standard of English teaching in secondary schools was "alarming", said one education official last week, arguing that if it continued unchecked it would be a serious setback to the government's plans to increase the number of scientists and technologists on whom the country depended for its future.

A concern for educational standards has also prompted the government to relax slightly the constraints placed on foreign university staff — exceptions are now frequently made to the ruling that a non-Malaysian can only be given two consecutive three-year teaching appointments — as well as the strong preference given to Malays in awarding university places over Chinese and Indian students with equal academic achievement.

The latter relaxation has proved to be controversial, particularly as many Malays see positive discrimination in their favour as necessary to eliminate the dominance of the Chinese in many professional fields, including scientific research.

For example, opening a conference on the role of universities in the developing countries last week, the vice-chancellor of the University Kebangsaan Malaysia, Professor Datuk Awang Had Salleh, said that solutions based on groups rather than individuals remained an appropriate strategy for university entrance.

## Erratum

The title of the article on the Indian environment, which appeared on page 207 of the 20 November issue of *Nature* should have been "Indian environment: Gandhi converted".

However, Malaya's Education Minister, Datuk Musa Hitam, is currently tightening up on the ease with which Malay students can at present enter university. In particular, he is reducing the proportion of Malay to Chinese and Indian students by 2 per cent a year until a final figure of 55 per cent *bumiputra* — literally "sons of the soil" — and 45 per cent non-*bumiputra* is achieved in the country's five universities. This is roughly equivalent to the racial balance in the country, but between 1970 and 1975, for example, the preference given to Malays increased their size as a proportion of student intake from 50 to 65 per cent.

Speaking at the opening of an educational building in Kuala Lumpur, Mr Datuk Musa was quoted as saying that this development should be taken as a "warning signal" to both *bumiputra* students and their parents that entrance to universities would in future depend less on their racial status and more on their academic achievement.

There is less political pressure to change the impact of present policies on the make-up of university staff. Part of the restructuring policy has been to increase considerably the number of Malay teachers and administrators in both schools and universities, again with the intention of redressing previous imbalances.

Chinese and Indian teachers accept both the logic of this policy and the political needs on which it is based. But in private, many express unhappiness that appointments, even at relatively senior administrative levels, are sometimes made with little respect for academic merit, and that in the process their own promotion prospects have been significantly reduced.

University staff in Malaya, however, are forbidden as government employees from taking part in any attempt to change policy. Lacking significant political power, their only options are frequently either to accept their reduced prospects or to seek teaching or research appointments abroad.

David Dickson

## Antarctic research

### Germany joins in

A bid for a voice in the future development of the Antarctic may be behind West Germany's massive new research programme in the area. Details published recently\* show that West Germany will become second only to the United States in the size of its investment in Antarctic research.

Although West Germany acceded to the Antarctic Treaty in 1979, it is still not admitted to the inner consultative group of countries which discuss matters beyond research, such as the exploitation of krill,

\*Antarktisforschungsprogramm der Bundesrepublik Deutschland, Bundesministerium für Forschung und Technologie, Bonn. An English summary is available.

one of the last great untapped food resources of the sea, and the development of possible offshore oil supplies. In the wording of the treaty, admission to the consultative group is reserved for the original 12 signatories (which did not include West Germany) and for any later signatory demonstrating its interest in Antarctica either by conducting substantial scientific research activity there — such as the establishment of a scientific station — or by the despatch of a scientific expedition.

Germany for blob in Weddell Sea

West Germany is doing both. It is creating a new 20-man research and training institute at Bremerhaven to direct its Antarctic programme, building a supply and research ship and purchasing one or two Lockheed C130 transport aircraft (the largest planes on skis). Its commitment will cost DM 385 million (£85 million) to the end of 1983, with a large fraction going on capital equipment and buildings.

The Bremerhaven centre will be called the "Alfred Wegener Institut für Polarforschung" after the originator of the concept of continental drift, who died on an expedition to Greenland in 1930. The institute will open in January 1981 under the directorship of Dr Gotthilf Hempel, a marine biologist now at the University of Kiel, while the research ship, which has been placed on order at a German shipyard, will be launched in 1982.

Officials at the federal research ministry were at pains last week to demonstrate West Germany's long research interest in Antarctica. Germans were among the first explorers of the polar continent, with expeditions in 1873, 1901, 1911 and 1938. The last expedition, according to some commentators, was not research but an effort by Hitler to establish a territorial claim and was overtaken by the events of the Second World War. The region explored at that time (called New Schwabenland and Queen Maud Land) is now claimed by Norway. After the war, West Germany was too preoccupied with economic reconstruction to bother with the Antarctic. Interest revived in 1975 when a research ship was sent to investigate krill.

## Antarctic politics

Antarctic politics are tortuous, a product of random historical and geographical factors and the current interest in food and oil resources. The Antarctic Treaty was set up after the International Geophysical Year of 1957–58, and ratified in 1961 by twelve nations: Argentina, Australia, Belgium, Chile, France, Japan, New Zealand, Norway, South Africa, the United Kingdom, the United States and USSR. Since then Bulgaria, Brazil, Czechoslovakia, Denmark, East Germany, West Germany, the Netherlands, Poland and Romania have acceded to the treaty, but of these only Poland has so far joined the all-important "consultative group" (which otherwise consists of the first 12 signatories). West Germany has applied to do so and is awaiting admittance.

The treaty forbids new territorial claims on Antarctica, but has no effect on previously asserted rights or claims. Before the treaty, Argentina, Australia, Chile, France, New Zealand, Norway and the United Kingdom had claimed sectors of the continent centred on the South Pole. These states recognize each other's claims, except Chile, Argentina and the United Kingdom, which have largely overlapping claims. The claims do not affect the placing of research stations: West Germany's proposed station will be on the edge of the Ronne ice shelf, near Berkener Island in the krill-rich Weddell Sea, on territory disputed between Argentina and the United Kingdom. The Antarctic Treaty confirms free access to all areas of Antarctica to all signatories. The legal status of the territorial claims, relevant only to resource development, is untested.

Surveys for an Antarctic research station began in 1979. The chosen site near Berkener Island is on the edge of the Ronne ice shelf, an extension of the Antarctic ice sheet over the shallows of the Weddell Sea. The station is now under construction and by late 1981 it will begin to serve as a scientific observatory for 45 scientists and technicians and a supply base for expeditions within a 1,000 km radius, wide enough to include the geologically interesting Palmer, Ellsworth, Pensacola and Shackleton mountain ranges.

Two other nations are also increasing their efforts in Antarctica — Australia and Argentina. Australia announced recently that it would completely re-equip its existing stations in Antarctica, at a cost of £20 million. Argentina is planning to construct the first all-weather, hard-surface landing strip as a potential refuelling base for commercial transpolar flights. Argentina is also constructing a new icebreaker for Antarctic work.

Robert Walgate

## Bangladesh

### Planning science

#### Dacca

Better use of the existing facilities and manpower for scientific research and development are given special attention in the Bangladesh government's Second Five-Year Plan, now published. In research and development, priority is given to agriculture, light and heavy industry, energy provision including nuclear power, housing and sanitation and transport.

The contribution of science and technology to the socio-economic development of the country has so far been relatively insignificant. Although Bangladesh boasts about 30,000 scientists and technologists with postgraduate qualifications, some 7,000 engineering graduates and more than 100,000 lower-level scientists, university research has often been "too academic" and in the government establishments research has often duplicated work done elsewhere. In nationalized industries there has been little initiative for innovative research, and in the private sector there has been virtually no research and development work.

#### Allocation for science and technology in the Bangladesh Second Five-Year Plan

|                                      | Estimated budget<br>(in millions of taka*) |
|--------------------------------------|--|
| Agriculture                          | 2,400                                      |
| Industry                             | 1,570                                      |
| Flood control and water<br>resources | 750  |
| Transport and<br>communication       | 210  |
| Health                               | 390  |
| Education                            | 50   |
| Natural resources                    | 260  |
| Nuclear power                        | 1,000                                      |
| Science, technology and<br>research  | 1,550                                      |
| Others                               | 200  |
| <b>Total:</b>                        | <b>8,380</b>                               |

\*US\$1 = 15.30 taka.

Main spending areas in the new plan (see table) are agriculture, industry, flood control and water resources, nuclear power plants and science and technology research. Of the allocation to science and technology research, nearly half of the 1,550 million takas budget goes to the Bangladesh Atomic Energy Commission. The bulk of the rest goes to the Bangladesh Council of Scientific and Industrial Research, the Space Research and Remote Sensing Organization and the Museum of Science and Technology.

The nuclear power programme includes a plan for the country's first research reactor for the production of radio-isotopes, a new 125-MW nuclear power plant in the western zone of the country and a study of the feasibility of extracting nuclear minerals from beach sand.

The space research organization is to concentrate on the completion of Bangladesh's advanced multipurpose

satellite ground station. The station's equipment is to be developed so that it can receive data from the various satellites including CMS (Japan), TROS-N and NOAT (United States) and METEOR (USSR). Important aspects of the satellite-based work for a developing country such as Bangladesh are a natural resources survey and a disaster-warning network. The five-year plan includes policy recommendations aimed at improving links between research centres and industry, improving primary and secondary education and giving further education a more practical bias. **M. Kabir**

### Soviet fertilizers

### Going it alone

Fertilizer production has been hived off from the Soviet Ministry of the Chemical Industry and now merits a ministry of its own, under Minister Aleksei Petrishchev, previously deputy chairman of the State Committee for Material and Technical Supply. At the same time, a new Minister of the Chemical Industry, Vladimir Listov, has been appointed. He was formerly deputy minister and has been working in the Party Central Committee since 1977.

These changes provide an indication of the direction of Soviet planning in the next five years, coming as they do in the closing weeks of the five-year plan. "Chemicization", as it is called, was launched by Khrushchev in 1958 and was continued by his successors. But Krushchev himself was less fond of chemical fertilizers than of the "virgin lands" — horizon-to-horizon grainfields in the erstwhile uncultivated steppelands of Asia. In 1965, his successors introduced a new agricultural strategy based on increased investment in agriculture, land improvement (drainage and irrigation) and an emphasis on intensive methods of cultivation, increasing the yield per hectare by the use of fertilizers rather than by expanding the total area cultivated.

The expansion of the chemical fertilizer industry was initially heavily dependent on Western technology, particularly the Pullman-Kellogg ammonia system and urea plants. Indeed, much of the capacity of these plants is still being used to pay off the cost of the equipment under compensation agreements.

Recently, however, the Soviet Union has been stressing its independence in all matters of chemical production. To some extent, this may be a reaction to world events. The main raw materials of the Soviet chemical industry are oil and natural gas, and the Gulf war has produced a spate of assurances that there is no oil shortage in the Soviet Union.

Poland is the Soviet Union's main supplier of another raw material vital to the fertilizer industry — sulphur. Political changes there may force Soviet planners to look more seriously at plans to utilize their

own relatively inaccessible sulphur beds.

Irrespective of politics, however, the Soviet fertilizer industry does seem to have reached a stage of relative technological independence. The new Chirchik ammonia plant, for example, is based on Russian technology and Russian contracting.

In spite of official emphasis on increasing the yield of food crops, Soviet agriculture's capacity for fertilizer remains far from satisfied. In 1976 only 50 per cent of the total grain cultivated area received any fertilizer at all.

The setting up of the new Ministry for the Production of Chemical Fertilizers strongly suggests that all branches of the fertilizer industry are to receive a boost in research and development. It also suggests that the forthcoming five-year plan will maintain the current emphasis on the "non-black-earth" regions in the west of the USSR, where the relatively poor soil demands considerable use of fertilizers.

If, as seems likely, the new ministry plans to build more fertilizer plants, the siting of these plants will be a major policy decision. At present, most plants lie in the non-black-earth zone, handy for the market, but far from Siberia, the main source of raw materials. Plants could, of course, be set up in Siberia, but the Siberian economy is in a bad way. **Vera Rich**

### European plutonium

### Project denied

#### Brussels

The future of the European Commission's support of research and development on plutonium cycling is in doubt. Last month, after a year-long search for a compromise, the Committee of Permanent Representatives (COREPER) rejected Euratom's second four-year plan even though this had been approved by the European Parliament last May. Officials now seem at a loss to know how an acceptable proposal can be devised.

The first programme ended in 1979 with what the commission described as "highly significant results" and encouraged it to draw up the more ambitious plan for 1980-84 now rejected. A total of 30 million European Units of Account (1 EUA = £0.56) was for research on the environmental effects of using plutonium (including the reprocessing of plutonium fuel), the transport of plutonium, the fabrication of mixed plutonium oxide and uranium oxide fuels and the recycling of used mixed-oxide fuels from light-water reactors.

France and the United Kingdom have led the opposition to the programme while Germany and Belgium have shown the greatest enthusiasm. The French and British are anxious to have cheap plutonium with which to fuel fast-breeder reactors and would rather buy plutonium from fellow member states than use recycled plutonium from their own reactors — the theory being that this would

increase the supply of plutonium and keep prices down.

Commercial rivalry is also said to have contributed to the rejection of the plan. The United Kingdom has already developed a process for fabricating mixed-oxide fuels and fears that a new research programme may compromise its capacity to collect royalties from the licensing of the process.

The desire to cut back on the commission's budget also probably contributed to the rejection of the programme, and thoughts are therefore now turning towards a "supplementary programme". Unlike a joint programme, this would be financed only by the interested countries.

Germany is committed to the plutonium-cycle programme because it wants to keep all options open, and public pressure at home makes any movement towards improving nuclear safety particularly attractive. Belgium, which generates 20 per cent of its electricity from nuclear power stations, feels that the programme would help towards securing steady fuel supplies. Italy and Holland seem prepared to go along with the programme but Ireland and Denmark are less sure — Ireland because it would draw little benefit in the foreseeable future and Denmark because it is interested only in the safety aspects of the plutonium cycle and would prefer the budget to be halved.

Jasper Becker

## Project planning

### Staged inquiries

The proposal that major planning issues of national importance, such as the fast-breeder reactor, should be decided in two stages, with a "project inquiry" followed by a local planning inquiry, was debated at a seminar on "The future of the big public inquiry" held at the Royal Institution, London on Monday 24 November.

The proposal has its origins in the work of a working party of the Council for Science and Society which issued a report in July 1979 recommending that project inquiries should investigate major proposals in depth, paying attention to the need for the project and considering all possible alternatives. One objective was to avoid lengthy and sterile wrangles at statutory local planning inquiries and even disruption by frustrated environmentalists.

There has recently been growing dissatisfaction with inquiries on national issues such as the building of major airports and motorways and nuclear installations. The siting of motorways seems to have been a particularly contentious subject and inquiries on such subjects have often been disrupted by highly regarded citizens.

The working party of the Council for Science and Society relied on the assistance

of Justice (the British section of the International Commission of Jurists) and the Outer Circle Policy Unit. The chairman was the barrister Paul Sieghart, vice-chairman of Justice, and the members were drawn from public administration, industry and planning.

At this week's meeting, Lord Kearton (with an extensive background of manufacturing industry) welcomed the proposal for preliminary project inquiries. He said few "big" inquiries were likely to arise in the near future and these would consist of proposals by the government for new motorways or for nuclear installations or refineries from bodies concerned with energy.

Sir Wilfred Burns, chief planner at the Department of the Environment, however, attacked the notion of the project inquiry. He argued that such a process would bring into question decisions reached democratically by parliament, the ultimate arbiter in matters of general policy.

The audience, consisting of officials, planners, consultants and members of pressure groups, seemed on the whole to have been in favour of the concept of a project inquiry. John Tyme, the veteran motorway protester, summed up the need for change by saying that many developers were "biased and ignorant, and many so-called experts on traffic or energy needs had been shown to be wrong".

Kenneth Mellanby

## French science museum takes shape

### Paris

The new French Museum of Science and Industry is at last beginning to take shape, even if at present only in the form of an architect's model. Two years after the commissioning of a report on the possibility of a new museum, and a year after that report was handed in, the final architectural plan has been selected. This pace, extraordinarily slow even for France, is a result of the problems attendant on a prestige project of this kind in a country in which "prestige" often equals "personal politics".

As originally conceived by the President of France, Valéry Giscard d'Estaing, the museum was to be the scientific equivalent, in grandeur and prestige, of the immensely successful Centre for the Arts created by his predecessor Georges Pompidou. To be erected on the 52-hectare site of La Villette in the north of Paris, the project was to be the largest, most modern science museum in the world. The original report, prepared by Maurice Lévy of the University of Paris, envisaged the conversion of an existing building on the site to a 100,000 square metre showplace of scientific and technical advance (*Nature*, 3 January).

Since then, however, a number of problems have surfaced which threaten to delay the project or to change it a great deal. There have been problems of money; the floor space available to the museum has

had to be reduced by more than half, to 40,000 m<sup>2</sup>; even so, the whole project is expected to cost 800 million francs — at a time of growing austerity in France. There have been clashes of personality; early in the year Lévy resigned as head of project, to be replaced after a three month interregnum by André Lebeau of the Conservatory of Arts and Crafts, an older, very traditional Paris museum.

Nor has the departure of Lévy ended all the differences of emphasis on policy questions among the museum staff. For example, the director of exhibitions, Goery Delacote, speaks of using the history of science and technology to "show the failures as well as the successes" so as to avoid a "triumphalist" conception of

science, while general director Lebeau maintains that "the historical dimension should be present more to enlighten the comprehension of contemporary science than to tell the story of past science".

Added to all this is the fact that President Giscard d'Estaing retains a final say over all aspects of the museum's planning. Nor is this merely a formality. It was the president who chose the design of the winning architect Adrien Fainsilber from among the seven preselected by an international committee.

Thus the problems of a multiplicity of power centres, ambiguities in conception and increasingly tight financial resources suggest that the new museum is in for a prolonged and difficult gestation period which may last beyond 1984, the proposed date of completion.

Jim Ritter

*Will Giscard, like Pompidou, have a centre . . . . . ?*

# CORRESPONDENCE

## Medical education

SIR — In the article "Medical schools stay" (*Nature* 6 November, p.6) you say that King's College Hospital Medical School is rerieved. The Flowers Report did not in fact envisage the closure of King's College Hospital Medical School but suggested a fusion with Guy's Hospital, the product to be called the Lister Hospital. This idea has been replaced by a proposal that King's, Guy's and St Thomas's Medical Schools should form a consortium of equal partners under a common management body.

The debate in the University is now centred on the possible closure of the Medical Faculty of King's College London, from which the majority of our pre-clinical students come. The University has set up a subcommittee of its Joint Planning Committee called the Medical Costing Committee which is urgently to review pre-clinical education in London and to report its findings by January 1981. From its report the Senate and Court of London University will be able to make a decision on where medical students will derive their basic scientific training in London.

## Risks at NRPB

SIR — Confidence in nuclear energy (*Nature* 19 June p.521) is not helped when individuals interested in the risks associated with it are inhibited either from expressing their opinions or from performing their work. The uninitiated who read the section on "Quality and integrity of the advisory and control authorities" in the Parker Report of the Windscale Enquiry would probably conclude that the record of the National Radiological Protection Board (NRPB) was clear in this respect, and moreover that although its late Director of Research, Dr G.W. Dolphin, in his generally censured paper on the Windscale workers, had underestimated radiation risks through a "mistake in methodology", the affair only showed that Dolphin was not infallible.

I have written (*New Scientist* letter, 13 January 1977) about the conditions at NRPB where my paper on radiation risks in the Japanese A-bomb survivors was held up by Dolphin for a year. One reason was his ignorance of statistics but he also objected strongly to risk estimates which were larger than he expected. The increases were not extraordinary but Dolphin's loyalties apparently remained with the Atomic Energy Authority (AEA) for he cautioned against making risk estimates which could be used against the fast breeder reactor. In contrast to the openly expressed bias supporting nuclear energy, there were no discussions about the possible risks from its development.

Before the merger forming the NRPB, the director of the Medical Research Council Radiological Protection Service publicly

warned staff, in the presence of the NRPB chairman and director elect, that the new management could not be trusted. Similarly, many of the AEA staff that joined the NRPB strongly distrusted the management who, they said, had abused their power in the AEA and exercised control over staff by, for example, making false reports on their work. However, they took care not to express any criticism in public and warned that it was futile to resist management decisions.

These management practices continued in the NRPB. Members of the staff found that it did not pay to disagree with the management who, in contrast, were apparently free to do as they pleased. When I objected to the management's duplicity and views on risks, the director of research warned that it would do me no good and became intent on making the conditions intolerable even at the expense of the work.

In 1977, soon after the Flowers Report made its criticisms of the NRPB, I wrote to Sir Edward Pochin, a member of the NRPB and an assessor at the Windscale Enquiry, concerning the working conditions at the Board but, although he promised to investigate, I received no reply. Recently my MP made enquiries and in the Board's answer it is claimed that Dolphin was the real author of the NRPB paper, published in my name, on risks in the A-bomb survivors, a statement which is clearly false from Dolphin's Windscale paper.

Evidently the regard shown to NRPB staff employed on similar projects depends primarily on who they are and not on the quality of their results. However, such anomalies do show the standard of the NRPB.

## Reagan a plus?

SIR — It is with a mixture of incomprehension, dismay and disgust that we read David Dickson's assessment of the "plusses and minuses" of the 1980 United States elections (*Nature* 13 November, p.107), where Mr Dickson notes completion of the Clinch River Fast Breeder Reactor and resumed production and stockpiling of chemical warfare agents as expected plusses of the Reagan election. Since when is the development of a questionable technology with very likely adverse ramifications for the environment and for attempts to limit nuclear proliferation a positive direction in which to proceed? Since when is the development of new tools of murder and mayhem a plus for anyone, or does *Nature* — or at least its Washington editor — hold the view that science prospers when humanity is threatened?

## Man's biosphere

SIR — I was sorry to see, in the unsigned editorial on Unesco (*Nature* 6 November, p.2), the passing reference to the Unesco "Man and the Biosphere Programme" as "chiefly valuable as sources of largely empty generalizations". Whoever wrote this editorial must have done so from a position of almost total ignorance of the MAB Programme. A research programme which has been endorsed by 79 countries, with more than 960 field projects, and involving more than 5,000 scientists is no empty generalization.

It is, of course, true that government departments and agencies in this country have shown relatively little interest once they have discovered that there is no "pot of gold" which can be readily tapped, as in the International Biological Programme. Nevertheless, scientists in research council institutes and in British universities have made, and are continuing to make, valuable contributions to the research of Third World countries in Asia, Africa and South America. They and their colleagues in these countries will be surprised, if not angry, at the glib dismissal of one of the most exciting and ambitious environmental research programmes as insignificant.

## Scientific warfare

SIR — R.A. Davis (*Nature* 6 November, p.8) has failed to notice that science and scientists do not exist in a social vacuum. Applications of technology generally raise questions concerning its impact on society and it is irresponsible for scientists to ignore these questions, especially when the technology concerned is to be applied to warfare.

One cannot help but be concerned when the US Army is interested in research directly related to chemical weapons, particularly since the recent go-ahead for the construction of a binary nerve gas plant. The United States is a signatory to several international agreements which specifically prohibit the use of these weapons — weapons which are indiscriminate in their effects upon noncombatants. To suggest that the development of an antidote will render these weapons useless is akin to suggesting that building fallout shelters makes the world safer from nuclear war.

It is incumbent on the participants of a democratic society to call attention to, and question policies which they do not believe serve the common good. When these participants are scientists and the policy concerns science then the pages of *Nature* are indeed the appropriate place to raise the issue.

## NEWS AND VIEWS

## Sun-climate links

from T. M. L. Wigley

DOES the Sun vary in ways which could affect our climate and, if so, are these variations sufficiently large to have noticeable effects? The question of the Sun's influence on climate was examined in detail at a recent conference\* where new data and recent advances in solar physics and Sun-climate links were presented.

If the Sun is to affect the Earth's climate, then some part of the Sun's output must vary. So far, the only variations observed seem unlikely to have a direct impact on climate. The solar 'constant' (that is the radiation output in the visible region, 300–400 nm, which accounts for 99 per cent of the Sun's energy flux) may not be a constant but evidence for its variability on annual and greater time scales is inconclusive. P. Foukal (Atmospheric and Environmental Research) reviewed this evidence and pointed out that changes have been observed directly only on shorter time scales; for example, those associated with the 27-day solar rotation period. The magnitude of these changes is extremely small, less than 0.1 per cent.

Longer-period and much larger-magnitude changes are well documented at shorter ultra-violet (UV) wavelengths. The magnitude of these fluctuations becomes larger as wavelength decreases, at least down to around 120 nm (Ly $\alpha$ ). D. Heath (NASA, Goddard Space Flight Centre) presented intriguing evidence that the direction of change over the past ten years has been different above and below 190–210 nm, with indications that these changes are associated with either the 11-year sunspot cycle, or the 22-year magnetic cycle.

Particle fluxes associated with the solar wind and recorded by their effect on the

Earth's magnetic field also follow the solar cycle. P. Simon and J. P. Legrand (Observatoire de Meudon and Laboratoire de Geophysique, EXTERNE-CNRS, Saint-Maure respectively) argued on physical and statistical grounds that the solar wind has two distinct components. The frequency of high-energy (10–100 MeV) proton events from solar flares and heliomagnetic disturbances, although the disturbances themselves are only short-lived (up to 100 min), varies approximately in phase with the sunspot cycle, while the lower-energy (around 1 MeV) particles emanating continuously from (mainly polar) coronal-hole regions show an out-of-phase relationship, the two combining to give a complex pattern of cyclic variations which is mirrored by variations in the Earth's magnetic field. These geomagnetic cycles have already been studied by Crooker *et al.* (*J. geophys. Res.* **82**, 1933, 1977) and by Feynmann and Crooker (*Nature* **275**, 626; 1978).

Just how UV and particle flux changes might affect climate is uncertain as direct effects, resulting from photochemical processes, are only observed in the stratosphere or above. We do not yet know how (or whether) these effects can be translated to the troposphere. Various mechanisms have been proposed (summarized by J. J. Berthelier, Laboratoire de Geophysique, EXTERNE-CNRS, Saint-Maure, and by A. P. Mitra, National Physical Laboratory, New Delhi) involving stratospheric aerosols, dynamic coupling between troposphere and stratosphere, changes in the Earth's electric field and/or direct radiative effects. These mechanisms are still speculative and require more detailed theoretical study and empirical testing; although the latter is hampered by the quality of currently available data. For example, although there is clear evidence that the solar proton event of 4 August 1972 affected stratospheric ozone, changes in ozone on longer (year-to-year) time scales have not yet been convincingly linked to solar activity (see Pittock *Rev.*

*Geophys. & Space Phys.* **16**, 400; 1968; Dutsch *J. atmos. Terr. Phys.* **41**, 771; 1979).

Statistical evidence of tropospheric changes associated with day-to-day solar variations was presented by J. M. Wilcox (Stanford University). Wilcox and his colleagues (see *J. atmos. Sci.* **33**, 1113; 1976) have found a relationship between the vorticity area index and the passage of solar magnetic sector boundaries, but the reality of this as a stable phenomenon has been questioned (Williams & Gerety *Nature* **275**, 200; 1978; Shapiro *J. atmos. Sci.* **36**, 1105; 1979). Russian work of a similar nature, reported by E. R. Mustel and co-workers (Astronomy Council of the Academy of Sciences of the USSR), apparently shows significant changes in surface pressure patterns 2 to 4 days after intense geomagnetic storms. Both of these phenomena are most evident in regions of large baroclinicity and in winter. It was suggested that this might imply some conditionally unstable initial condition in the atmosphere which is triggered in some way by a solar event, although recent modelling work by B. G. Hunt (*J. geophys. Res.* in the press) does not support this hypothesis. Further work is required before the reality of these short-term Sun-weather links is firmly established.

On the decadal time scale, tropospheric effects associated with the 11- or 22-year solar cycle remain controversial (see Pittock *Rev. Geophys. & Space Phys.* **16**, 400; 1978; *Nature* **283**, 605; 1980) and lack causal links. Interesting statistical relationships shown by R. G. Vines (CSIRO Division of Chemical Technology) and by C. J. E. Schuurmans (Royal Netherlands Meteorological Institute) (see also Schuurmans *Climatic Change* **1**, 231; 1978) point to a solar influence on the general circulation and may relate to the

T. M. L. Wigley is in the Climatic Research Unit, University of East Anglia, UK.

\*'Sun and Climate', Toulouse, France, 30 September – 3 October was sponsored by the Centre National d'Etudes Spatiales, Centre National de la Recherche Scientifique and the Délégation Générale à la Recherche Scientifique et Technique. The proceedings of this conference will be published by the Centre National d'Etudes Spatiales as a companion volume to *Evolution of Planetary Atmospheres and Climatology of the Earth* (the proceedings of a conference in Nice in 1978; *Nature* **276**, 213; 1978).

recent solar-jet stream link found by Nastrom and Belmont (*J. geophys. Res.* **85**, 443; 1980).

On the century time scale, it was suggested long ago (de Vries *Koninkl. Ned. Akad. Wetenschap. Proc. B* **61**, 98; 1958) that changes in atmospheric  $^{14}\text{C}$  levels might reflect changes in solar activity and climatic change. This idea was cautiously revived by Eddy (*Climatic Change* **1**, 173; 1977), and recent work by Stuiver and Quay (*Science* **207**, 11; 1980) has quite firmly linked changes in atmospheric  $^{14}\text{C}$  to solar wind changes. Atmospheric  $^{14}\text{C}$  changes also run roughly parallel to the envelope of solar activity as measured by the mean number of sunspots over a sunspot cycle. The Maunder minimum (1645 to 1715), a period of reduced solar activity, was a time of high atmospheric  $^{14}\text{C}$ .  $^{14}\text{C}$  fluctuations like that seen during the Maunder minimum have occurred frequently in the past and further observations were presented by H. E. Suess (University of California, San Diego, see also *Endeavour* **4**, 113; 1980). We can thus be fairly certain that the Sun does vary on the 100-year time scale. Conclusive proof could come from measuring the minute concentrations of cosmogenic  $^{10}\text{Be}$  found in ice cores, using accelerator spectrometry (G. M. Raisbeck and F. Yiou, Laboratoire Renais Bernes du Centre de Spectrométrie, Nucleaire). Although these isotopic ( $^{14}\text{C}$  and  $^{10}\text{Be}$ ) variations do not in themselves indicate changes in solar output in the visible part of the spectrum, there is some indirect evidence of such changes. Changes in the Sun's radius should be accompanied by changes in luminosity (Sofia *et al. Science* **204**, 1306; 1979) and

radius changes can be calculated from eclipse data. Using material from the eclipse of 3 May 1715 collected originally by Sir Edmund Halley, NASA scientist, S. Sofia (Goddard Space Flight Centre), suggested that the Sun was about half an arc second bigger (and thus brighter) in 1715 than today. However, Parkinson (*New Scientist* 24 April, p203, *Nature* in the press;) has also examined eighteenth century eclipse data and deduces no changes in solar radius.

The link between atmospheric  $^{14}\text{C}$  activity and the Sun is through the solar wind, and does not yet encompass changes in the solar constant. A statistically significant link between  $^{14}\text{C}$  and climate had not yet been established either, in spite of the rough coincidence in timing between the Maunder minimum and the Little Ice Age. Thus, as for shorter time scale solar fluctuations, the Sun-climate link on the century time scale is still not proven. Recent work by Stuiver (*Nature* **286**, 868, 1980) has revealed only a few, barely significant correlations between reconstructed variations in solar activity (based on atmospheric  $^{14}\text{C}$  variations) and climate data over the past 1,000 years. Results presented by L. D. Williams (University of East Anglia), T. M. L. Wigley and P. M. Kelly extend the analysis to the past 4,000 years and to a wider range of proxy climate variables, but still fail to find any statistically significant relationships. The main problem now is with the climate data base. On the 100-year time scale, our knowledge of the details of climatic change over the past millennia is very sketchy. As more palaeoclimatic information becomes available, the picture of past climates

becomes more and more complex. Although many significant fluctuations, similar qualitatively if not in magnitude to the Little Ice Age, have clearly occurred in the past, it is also evident that the response to solar forcing would involve circulation changes which might lead to considerable differences in trend and timing of, for example, temperature changes from place to place.

Changes in the Sun and in the Earth's climate on time scales significantly greater than 100 years, while of less immediate importance to mankind, are nevertheless fundamental to the understanding of the workings of the Sun and the climate system. Since the first solar model of J. Homer Lane in 1869, and especially in the last decade, solar physics has progressed enormously (reviewed by I. W. Roxburgh, Queen Mary College, London). The faintness of the youthful Sun (with luminosity only about 70 per cent of today's), predicted by stellar evolution theories is now quite firmly established and has led to a greater understanding of the importance of changes in atmospheric composition in determining changes in climate on the  $10^9$ -year time scale (Owen *et al. Nature* **277**, 640; 1979). But, as pointed out by M. B. McElroy (Harvard University), this factor is equally important today because of the large anthropogenic input of  $\text{CO}_2$  resulting from fossil-fuel burning.

On intermediate time scales, between the century time scale variations implied by  $^{14}\text{C}$  data and the long-term stellar evolution trend in solar luminosity, the possibility of fluctuations in the Sun's output is speculative yet still important. J.-C. Duplessy and A. Berger (CNRS, Gif-sur-Yvette) reviewed respectively the observational and astronomical evidence for the Milankovitch theory, which relates the periodic glaciations of the past few million years to changes in Earth orbital parameters. Although the evidence for this theory is very strong, it is still difficult to explain how the small total changes in incoming radiation, which result from orbital changes, can produce such major climatic effects. The key lies in the nature of orbit-related changes in radiation input, which occur not in total input, but in the seasonal and latitudinal distribution of incoming radiation. Although the global average change in radiation is only 0.1% or less, local variations of more than 10% can occur and the effects of even small changes can be amplified by ice-albedo and other feedbacks.

A more significant problem with the Milankovitch theory is that the observational data available for the past 400,000 years shows the strongest periodicity of radiation at 100,000 years with lesser peaks at around 40,000 and 20,000 years (Hays *et al. Science* **194**, 1121; 1976), while the astronomical data implies that the 100,000-year peak should be relatively less prominent. Hays *et al.*

## 100 years ago

Herr V. Bergso, in a recent work, "Fra Mark og Skov," has given some interesting data in regard to the habits of the Tarentula, *Lycosa tarentula*, Latr., whose nests he has traced and examined on the Roman Campagna. He found that the nest, which was well rounded and smooth, was approached by a tunnel which, after running about a foot straight down below the surface of the ground, made a sudden short turn before it finally descended for about another foot into the spider's abode. The superstitious error of assuming that the bite of the animal induces an irresistible desire of dancing is due to the fact, that dancing having been originally employed as a remedy against the poison, which is believed to be eliminated by profuse perspiration, the action of the poison was confounded with the means of its eradication.

"We the undersigned, captain, officers, and crew of the barque *Pauline* (of London) of Liverpool, in the county of Lancaster, in the United Kingdom of Great Britain and Ireland, do solemnly and sincerely declare that on July 8,

1875, in lat.  $5^{\circ}3'$  S., long.  $35^{\circ}$  W., we observed three large sperm-whales, and one of them was gripped round the body with two turns of what appeared to have a length beyond the coils of about 30 feet, and its girth 8 or 9 feet. The serpent whirled its victim round and round for about fifteen minutes, and then suddenly dragged the whale to the bottom head first.

"GEORGE DREVAR, MASTER  
"HORATIO THOMPSON  
"JOHN HENDERSON LANDELLS  
"OWEN BAKER  
"WILLIAM LEWARN

"Again, on July 13, a similar serpent was seen about 200 yards off, shooting itself along the surface, head and neck being out of the water several feet. This was seen only by the captains and one ordinary seaman, whose signatures are affixed.

"A few moments after it was seen elevated some sixty feet perpendicularly in the air by the chief officer and the following able seamen, whose signatures are also affixed —

"HORATIO THOMPSON  
"WILLIAM LEWARN

"And we make this solemn declaration, &c.  
"Severally declared and subscribed at Liverpool aforesaid the 10th day of January, 1877, before

"T. S. RAFFLES, J.P. for Liverpool."  
From *Nature* **23**, 25 November, 84, 1880.

suggested that this may be related to a non-linear response. Two different explanations were presented here. C. Nicolis (Institut d'Aeronomic Spatiale, Belgium) presented a very simple model which showed how internal feedbacks could amplify an otherwise weak 11- or 22-year sunspot-related signal. A very different model developed by J. Oerlemans and J. M. Bienfiet (Royal Netherlands Meteorological Institute; see also *Nature* 287, 430; 1980) also produces a 100,000-year periodicity in the climate record, but in this case resulting entirely from internal factors related to isostatic rebound. This interesting result may, paradoxically, support the

Milankovitch theory. The strength of the 100,000-year periodicity is not constant and almost vanishes about  $10^6$  years BP. This would be hard to understand if the cause were purely internal, but less so if climatic changes were the result of orbital forcing. The lack of a 100,000-year periodicity in the early climate record may be related to the fact that perennial sea-ice cover in the Arctic only began around 700,000 years ago (Margolis and Herman *Nature* 286, 145; 1980). However, it may well be that around  $10^6$  years BP, the orbital parameters themselves, if more accurately known, have no 100,000-year signal.

deep in northern latitudes) or thinner blankets in persistent oceanic, montane or tundra conditions. In the tropics peat is normally located in badly drained, riverine and coastal flats but can also occur in wet, cool climates at high altitudes. Tropical peats are usually deeper (up to 20m or more have been recorded) and contain many more macro-remains of vegetation plus mineral matter than their temperate counterparts.

The value of peat as an alternative energy source has perhaps been under-assessed and a broad spectrum of work is now being undertaken to harness its potential more effectively. Canadian authorities estimate that there is more energy potential in their peat deposits than in their forests or their reserves of natural gas. The National Energy Board calculates Canadian peat reserves at 89 billion tons which is equivalent to 500 trillion cubic feet of natural gas. The peat reserves of the US are put at 13 billion tons and the US Department of Energy has recently allocated \$2.2 billion for the development of alternative fuels, including peat as a major component. In the USSR peat fuels no less than 76 large electric generating plants. The Republic of Ireland generates one-third of its electricity and one-fifth of its total energy requirement from peat. Finland is in a stage of rapidly advancing technology in this field and it is estimated by 1990 that up to 8 per cent of the national energy requirement will be met from peat. Peat consumption in Europe has reached a point where regional producers cannot meet the demand. In the United Kingdom,

## Peat — a resource reassessed

from J. A. Taylor and R. T. Smith

REPORTS at the Sixth International Peat Conference\* suggest a need for a fundamental reassessment of the world's peat resources in industrial, agricultural and environmental terms. The total area of the world's peatlands is now estimated to be about 500m ha, equivalent to an area over half that of the United States. Canada (150m ha, 36%) and the USSR (170m ha,

40%) together monopolize over three quarters of the world's peatlands but there are also extensive tropical peatlands in the lowlands of S. America, Central Africa and parts of SE Asia.

Peat is organic matter derived from the slow decay of plant remains by the action of bacteria and fungi. Decay is finally arrested in the absence of free oxygen and sunlight, normally under conditions of ground or soil waterlogging which may be aided by an accompanying wet and cool climate. Peat may thus accumulate in badly drained basins forming mires (up to 10-m

J. A. Taylor is University Reader in Geography, University College of Wales, Aberystwyth and R. T. Smith is a Lecturer in Geography, University of Leeds.

## Genes controlling cell proliferation

from Paul Nurse

AN attractive hypothesis for the control of eukaryotic cell proliferation is that it is regulated at a particular point during the  $G_1$  period before the initiation of DNA replication. This  $G_1$  control has been called the 'restriction point' in mammalian cells (Pardee, A. B. *Proc. natn. Acad. Sci. U.S.A.* 71, 1286; 1974) and 'start' in the budding yeast *Saccharomyces cerevisiae* (Hartwell, L. H. *Bact. Revs.* 38, 164; 1974; *J. Cell Biol.* 77, 627; 1978). Cells made quiescent in a variety of ways become blocked at this  $G_1$  control point, and cells shifted to conditions favouring proliferation have to pass this point before they become committed to the mitotic cell cycle. The control has been investigated genetically in *S. cerevisiae* by Hartwell and his colleagues, who have identified a gene *cdc 28* whose function is required before 'start' can be traversed. These workers

have suggested that before a cell traverses 'start', it monitors various conditions such as cell size, nutrient level, and the presence of conditions promoting conjugation and sporulation. If these conditions are satisfactory for cell proliferation, the cell begins a new mitotic cell cycle, but if they are not, the cell either becomes quiescent and enters stationary phase, or differentiates and undergoes conjugation or sporulation.

A recent study that has extended this genetic analysis in *S. cerevisiae* is described by Sudbery, Goodey and Carter in the current issue of *Nature* (p 401). They have isolated a novel series of mutants defining two *whi* genes, which undergo bud emergence and cell division at a reduced cell size compared with wild type. The *whi 1* mutants show a reduced cell size both during exponential growth and in stationary phase, whilst the *whi 2* mutation has a major effect only in stationary phase. When these mutants are made quiescent by deprivation of nutrients, they do not enter

stationary phase by becoming blocked at 'start'. They stop increasing in mass but they continue to initiate new cell cycles and to undergo division. When they eventually do stop proliferating, they are of a reduced cell size and have a reduced cell viability compared with wild type, and are also blocked in later stages of the cell cycle than the normal block point 'start'. These mutants are clearly defective in the gene functions required for an orderly transition of cells from the proliferating state to the quiescent state.

It has been suggested that mammalian cells may become malignant if they lose their 'restriction point' control (Pardee op. cit.), and as a consequence cells fail to accumulate at the proper point in  $G_1$  when shifted to conditions favouring quiescence. If this is the case, then the *whi* mutants may be analogous to some types of malignant cell lines. Therefore, the further study of the *whi* and *cdc* 'start' mutants may also have implications for the problem of malignancy in mammalian cells.

Paul Nurse is in the School of Biological Sciences, University of Sussex.

the peat cover is quite extensive but to date has been regarded as too thin, too variable, too remote (that is, in the uplands) and not economically harvestable — a situation that may change with the introduction of new technology.

The most costly and time consuming aspect of peat exploitation is the treatment of the peatland before harvesting and the initial winning and drying of the peat. The technology for these purposes already exists, thanks to forest industries which have already solved many of the problems of mire drainage. In northern lands the short harvesting season has led to much effort being put into mechanization and into improving techniques to remove the water from either sods or milled peat. In Sweden, a centrifugation and belt press process has been developed which can process 6 cubic metres of peat slurry per hour down to 50 percent dry substance (that is, water content reduced to 50 per cent by weight). From Finland comes a method of de-watering peat — the wet carbonization process — which produces dry pellets of partly carbonized peat, perhaps the most marketable product of the peat industry. Milled peat production is becoming more adaptable to mechanization, and subsequent processing is far and away more prevalent than traditional sod peat cutting. However, Finnish experience suggests that on the local scale at modest production, sod peat enterprises are likely to remain the more cost-effective. Peat is a most inconvenient source of energy compared to gas or oil but various gasification and liquefaction schemes are currently being tried out and may lead to major improvements. In these schemes processing plants will be located on the peat lands themselves as they are usually at great distances from centres of energy consumption. Peat-burning power stations, operated mainly by briquette peats, are commercially successful in the Soviet Union, Finland and Ireland but because of the variable consistency and calorific value of the peat, such stations are at least 5 percent less efficient than coal-fired ones.

As well as its value as an energy source, there appear to be many potential uses of peat as a raw material. Successful attempts have been made to use peatland for sewage disposal, on account of its great absorption capacity and its effectiveness in sequestering metallic cations. Other uses of peat include its role in activated carbon manufacture as a catalyst when treated with heavy metals, as a source of pharmaceutical and curative preparations, as a possible starting point for fertilizer manufacture, as a soil conditioner and even as a food additive.

The revaluation of the commercial potential of peat raises the question of the

possible harmful effects of its exploitation. The vast areas of peat function as stores of carbon, Bramryd (University of Lund) estimating that the annual average global rate of peat accumulation is 0.7mm — equivalent to about  $0.21 \times 10^{15}$  gC. Clearly, large-scale exploitation of peat and, in northern latitudes, interference in the fragile tundra ecosystem could help to trigger changes in the CO<sub>2</sub> balance. Only 10 per cent of the world's middle-latitude mires, mostly in Europe, USSR, USA and Canada, remain untouched. Accessibility for peat extraction and agricultural and

forestry development has been their demise.

New surveying techniques of peatlands are involving remote sensing, satellite imagery and georadar, notably in Sweden (Ultiksen, Lund Institute of Technology) the US (Hagen & Meyer, Minnesota Department of Natural Resources) and Scotland (Robertson, Macaulay Institute of Soil Research, Aberdeen). Automated monitoring of peatlands will boost not only scientific research into mires but also, ironically, their commercial exploitation in 'non-renewable' fashion.

## Photochemical conversion and storage of solar energy

from Professor Sir George Porter, FRS

PHOTOCHEMICAL decomposition of water into its elements is potentially of great importance. It is theoretically possible in sunlight with efficiencies exceeding 10 per cent, and there are several routes to success which seems tantalizingly close. Yet so far, no satisfactory and efficient system has been discovered. This is the stuff that photochemists' dreams are made of and it is not surprising that many of them are now as excited as the molecules which characterize their craft.

The Third International Conference on 'Photochemical Conversion and Storage of Solar Energy' brought together most of the active research workers in this field under the Colorado sun and appropriately close to the new Solar Energy Research Institute which sponsored the very successful and well organized conference on photochemical conversions held in September. One hundred and fifty papers were presented, either as plenary lectures or as posters, all of which were on view and open for discussion throughout the week — a most satisfactory arrangement.

It was clear from the beginning that the principal interest of the participants would be in the rapidly developing subject of the conversion of light into chemical potential by methods which, although inspired by the mechanisms used in natural photosynthesis, are entirely abiological or artificial or, if you must, 'biomimetic'. Dr Mary Archer's (University of Cambridge) review of photogalvanic cells for electrical-power generation was decidedly pessimistic and there have been no significant advances in the use of photochemical reactions for the storage and release of

thermal energy. On the other hand, liquid-junction photovoltaic cells are developing rapidly and appear quite promising.

The photochemical reaction which attracts most attention at present is the production of hydrogen and oxygen, by the visible-light photolysis of water. The methods by which this desirable objective might be achieved range from biological ones, which retain some part of the *in vivo* system, for example isolated chloroplasts, through completely homogeneous photochemical reactions in solution to photoelectrochemical cells with one or two semiconductor electrodes, of the type originally used by Fujishima and Honda.

The apparently large gap between the last two is now, however, bridged, first by the use of colloidal metals and semiconductor suspensions in solution and, second, by the use of 'photochemical diodes' which consist of 'wireless' particles in which the two electrodes, usually a metal and a semiconductor, are in direct contact in a single entity which may be microscopically small. There is now an almost continuous transition between these different approaches and much success is being achieved with photochemical electron-transfer reactions in solutions which contain suspensions of such catalytic particles.

One of the principal difficulties in bringing about the liberation of gaseous hydrogen and oxygen in electron-transfer reactions in solution has always been that hydrogen requires the accumulation of two electrons while oxygen requires the accumulation of four. In an electrochemical cell these processes occur

Figure 1: Photochemical reaction system

\*The Sixth International Peat Congress was held in Duluth, Minnesota from August 17th to 23rd, 1980. Over 600 delegates from 25 countries attended, including, for the first time, scientists from China, Japan, New Zealand and Burundi.

at the electrodes and, if the overpotential is to be made as small as possible, platinum is usually preferred for hydrogen liberation at the cathode and ruthenium dioxide for oxygen liberation at the anode. The most important advance of the last few years has been the discovery that suspensions of these two substances will catalyse the evolution of hydrogen and oxygen in homogenous solution. Recent progress was reviewed by two of the principal contributors to this progress, Jean Marie Lehn (Strasbourg) and Michael Gratzel (Lausanne).

The natural photosynthetic system carries out the oxidation and reduction in separate steps, with a redox couple of quinone/hydroquinone between them, and most research has been concerned with one or other of these processes, using a sacrificial donor for the hydrogen elimination and a sacrificial acceptor for the oxygen liberation half-reactions. The water reduction reaction has been studied in many laboratories, nearly all of which use the system shown in Fig. 1.

$MV^{2+}$  is methyl viologen (paraquat), which acts as electron carrier, and the sacrificial donor is usually EDTA, although many other substances which are irreversibly oxidized are equally satisfactory. As sensitizer, ruthenium

Figure 2: A four component system for the photochemical decomposition of water

trisbipyridyl has been most popular but water-soluble porphyrins have been used more recently and have many advantages; quantum yields of hydrogen production as high as 60 percent in green light were reported with zinc tetramethylpyridyl porphyrin as sensitizer.

The oxidation half-reaction, liberating oxygen, is in a less satisfactory state and, although ruthenium dioxide does act as a catalyst and liberates oxygen in the presence of an electron acceptor of sufficiently high redox potential, overall yields are low. Most surprisingly however, Gratzel and Kalyanasundaram reported oxidation and reduction with the simultaneous evolution of hydrogen and oxygen in a single system without sacrificial

electron donors or acceptors. The system was of four-components containing both catalysts, with methyl viologen as carrier and ruthenium trisbipyridyl as sensitizer (see Figure 2).

Of course, the liberation of hydrogen and oxygen together is not altogether desirable. Yields are low and the mechanism is not clearly understood; if confirmed it must obviously involve some specific kinetic selectivity of the redox components for the two catalysts.

In a highly competitive and developing field of research, preliminary reports which await confirmation are not uncommon. But this was a stimulating symposium in which everybody shared the excitement of a rapidly developing science.

Professor Sir George Porter, FRS, is Director of The Royal Institution

## Far-infrared interstellar carbon

from a Correspondent

IN interstellar clouds, carbon is taken up partly in dust grains and partly in the gas phase, where it is distributed between ionized carbon  $C^+$ , neutral carbon  $C$  and various molecules, mostly carbon monoxide with lesser amounts of other compounds such as  $HCN$ ,  $H_2CO$ ,  $HCO^+$ ,  $CH$  and  $CH_2$ . Because  $CO$  is widely taken as a measure of the densities of clouds in which  $H_2$  is the major constituent, the fraction of  $C$  existing as  $CO$  is a critical parameter in the determination of the cloud masses.

Observations of  $CO$  also provide information on the galactic isotopic ratio of  $^{12}C$  and  $^{13}C$  but, because of chemical exchange reactions, the relationship between  $^{12}C$  and  $^{13}C$  and the parent  $CO$  molecules depends, through a complicated chemical reaction scheme, on the density, temperature and age of the clouds. Information on the abundances of  $C$  and  $C^+$  would thus help to make more certain the estimation of cloud masses.

Most of the radiant energy emitted by the gaseous component of interstellar clouds is contained in fine-structure transitions of  $C$  and  $C^+$  and rotational transitions of  $CO$ . Emissions in the 1-0 and 2-1 rotational transitions of  $CO$  have been

measured at 1.3 and 2.6 millimeters, but it is the higher-lying transitions in the sub-millimeter region which contribute most of the cooling.

Recently the  $^3P_1$ - $^3P_0$  fine-structure transition of neutral carbon, the  $^2P_{3/2}$ - $^2P_{1/2}$  fine-structure transition of ionized carbon and the 6-5 rotational transition of  $CO$  have been detected from interstellar space. Laboratory measurements at the National Bureau of Standards using far-infrared laser magnetic resonance (R.J. Saykally and K.M. Evenson *Ap. J. Lett.* **238**, L107; 1980) established that the  $^3P_1$ - $^3P_0$  transition of  $^{12}C$  has a frequency of 492.1623(7) GHz (and that the  $^3P_2$ - $^3P_1$  transition has a frequency of 809.3446(29) GHz). These accurate measurements made possible a search for and led to the discovery of the  $^3P_1$ - $^3P_0$  emission from several molecular clouds in the interstellar gas (T.G. Phillips, P.J. Huggins, T.B.H. Kuiper and R.E. Miller *Ap. J. Lett.* **238**, L103, 1980). The detection system used an InSb heterodyne bolometer receiver. The bandwidth is only 1 MHz and several observations were necessary to record a single Doppler-broadened spectral line.

A heterodyne system has also been used,

but with a GaAs mixer diode, to observe the 6-5 rotational transition of  $CO$  at 692.9495 GHz (P.F. Goldsmith, N.R. Erickson, H.R. Felterman, B.J. Clifton, D.D. Pack, P.E. Tannenwald, G.A. Koept, D. Bull and N. McAvoys, *Ap. J. Lett.* in the press) in emission from the Kleinman-Low plateau source in the Orion molecular cloud.

The  $^2P_{3/2}$ - $^2P_{1/2}$  transition of  $C^+$  has a frequency of 1910 GHz and it has been detected towards the interstellar regions NGC 2024 and M42 (R.W. Russell, G. Melnick, G.E. Gull and M. Harwit *Ap. J. Lett.* in the press). The Cornell group used as a detector a stressed Ge:Ga photoconductor, cooled to 2K by pumping with liquid helium coolant, and a grating spectrometer (J.R. Houck and D. Ward, *Pub. A.S.P.* **91**, 140, 1979).

These papers demonstrate that a new region of the electromagnetic spectrum is accessible to observation. Sub-millimeter astronomy permits the direct observation of the major energy losses from the gaseous components of many regions of the interstellar gas and will provide powerful diagnostic probes of the physical environment in interstellar clouds where star formation is in progress.

# Microbial degradation of xenobiotic compounds

from Philip R. Lehrbach

MOST organic compounds released into the environment are rapidly broken down by the activities of fungi and bacteria. However, certain man-made compounds (xenobiotics) are not quickly degraded. Public concern over the persistence of such compounds stems from their accumulation in food chains and their toxicity to living organisms. Xenobiotics in the form of pesticides, dye stuffs, surfactants and the waste products of industrial processes require detoxification before they are allowed to enter the environment and new techniques are needed to bring this about.

At a recent meeting\* convened to discuss the capabilities of microbes and microbial communities to degrade exotic compounds, several strategies were considered from the viewpoints of industrial chemists, microbiologists and molecular biologists. H. Bretscher (Ciba-Geigy, Basel) discussed various methods for the total chemical and physical destruction of many xenobiotic compounds. Thermal degradation at incineration temperatures of 1,100°C, and the less developed but lower energy-consuming wet air oxidation (300°C) process were mentioned. But these processes have the disadvantages of high-energy expenditure and the total destruction of a potentially useful resource. In the future, economic constraints may dictate the use of biotechnical methods for the treatment of effluent. Such methods would be aimed at eliminating the environmental dangers while providing the basis for recovery of useful organic compounds used in the production of chemicals or microbial proteins.

Procedures are available (batch or continuous culture) for the isolation of bacteria or fungi able to grow on a particular organic compound. However, it is difficult to adapt these isolates so that they perform the same degradative function in the complex mixture of organic chemicals and salts present in industrial effluent. Reviewing the topic, W. Harder (Rijksuniversiteit Groningen, Haren) said that failure to isolate a pure culture able to utilize a particular compound may indicate that metabolism involves a community of bacteria and/or fungi. Important parameters such as culture conditions, interfaces, salt or acid gradients may have been overlooked. One example among many which illustrates the complexity of degradative processes is dichlorodiphenyltrichloroethane (DDT) metabolism. DDT is slowly broken down anaerobically to *o*-dichlorophenylmethane by

*Aerobacter aerogenes*. This compound is then co-metabolised by *Hydrogenomonas* to other less-toxic, chlorinated compounds.

One approach to the problem of waste disposal (D. Munnecke, University of Oklahoma), which applies a detailed knowledge of enzyme technology but eliminates the frailty of the living organism, is to supply the appropriate inactivating enzyme to a contaminated area. Such an approach has been taken to detoxify contaminating amounts of the insecticide parathion from liquid waste effluent and industrial or domestic containers. In this case parathion is detoxified to *p*-nitrophenol in the presence of the enzyme hydroxylase. This enzyme can be used successfully in soluble (whole cell or partially purified) or immobilized (glass matrix) form. This example serves as a useful model for the development of other enzyme systems. However, several limitations are placed on this method of waste disposal. The enzymes used must be readily obtainable at relatively low cost, simple in their application particularly for domestic uses, stable, and not require an expensive cofactor to function. To justify this approach the chemicals to be inactivated must be of considerable environmental and public hazard (as was the case with parathion). The quantity and dispersal of the compound must be sufficient to require a concerted effort for its eradication.

U. Gasche (Cellulose Attishelz, Luterbach) and H. Kern (Institut für Botanik und Microbiologie, Jülich) focused on the complex problems of dealing with effluents from cellulose manufacturers. To achieve high yields of cellulose fibres, mechanical and chemical treatment of wood is necessary to convert lignin into physically and chemically altered derivatives which become a predominant by-product in the effluents. Lignosulphonates are lignin products formed in the acidic sulphite pulping process and are more resistant to microbial degradation than lignin itself. H. Kern discussed the possibility of enzymatic removal of the sulphonate acid groups and the subsequent bio-oxidation of the desulphonated products. He quoted data of Ban *et al.* (*Biotechnol. Bioengng* 21 1917; 1979) on mixed cultures containing yeasts and bacteria as an approach to economically feasible processing systems.

An understanding of the numerous biochemical pathways necessary for the bacterial degradation of various organic compounds is well advanced. Several participants suggested that this knowledge

could be used to develop bacteria with new metabolic capabilities. The reasoning is that bacteria able to degrade organic compounds that are structurally related to xenobiotics may be 'modified' to metabolize these new compounds. Modification using established mutation/-selection procedures or the specific genetic manipulation of appropriate genes determining catabolic enzymes to form new biochemical pathways were suggested. Such an approach has already been taken in the construction of haloaromatic-utilizing bacteria (H.-J. Knackmuss, Institut für Mikrobiologie, Göttingen, see *Nature* 277, 385; 1979). A similar approach was suggested from an appreciation of the metabolic diversity of methane-utilizing bacteria (methanotrophs) (I. J. Higgins, D. J. Best and R. C. Hammond *Nature* 286, 561; 1980).

Several important recent developments in molecular biology make this approach attractive to biotechnologists and may aid in the industrial exploitation of these organisms. First, the discovery that many catabolic pathways, including the degradation of substituted aromatic compounds (toluene, xylenes, naphthalene and styrene), are determined by the presence of transmissible plasmids. This makes possible the transfer of metabolic capabilities between various Gram-negative bacteria. Second, powerful new *in vivo* and *in vitro* techniques for the analysis and manipulation of genetic material permit rapid characterization of the structure and regulation of important degradative pathways, precise manipulation of the expression and the construction of multipathway organisms. The recent development of suitable vector systems in *Escherichia coli* and *Pseudomonas* (M. Bagdasarion and K. Timmis, Max-Planck Institut für Molekulare Genetik, Berlin) make this approach feasible.

The molecular analysis of the plasmid involved in the degradation of toluene and xylenes (the TOL plasmid) is probably the most advanced. F. H. C. Franklin and K. Timmis (Max-Planck Institut für Molekulare Genetik, Berlin) presented a functional map of the catabolic enzymes of the TOL plasmid based on the phenotypic properties of Tn5 (kanamycin resistance) insertion mutants. In this manner three genes, including the *xylE* gene encoding 2, 3-oxygenase, were located. A subsequently cloned *XhoI* restriction fragment (*XhoI*-I) verified these data and showed expression of catechol 2, 3-oxygenase activity in the *Pseudomonas* host strain. These and similar studies on various catabolic plasmids will provide important information for the future construction of organisms capable of the specific degradation of xenobiotic compounds. □

\*The 12th FEMS symposium on 'Microbial Degradation of Xenobiotic and Recalcitrant Compounds' held at Zürich, 15-19 September 1980. The proceedings will be published by Academic Press.

Phillip R. Lehrbach is in the Department of Molecular Biology, University of Edinburgh.

## X-ray properties of quasars

William H.-M. Ku, David J. Helfand &amp; L. B. Lucy

Columbia Astrophysics Laboratory, Departments of Astronomy and Physics, Columbia University, 538 West 120th Street, New York, New York 10027

*The X-ray properties of 111 catalogued quasars have been examined with the imaging proportional counter on board the Einstein Observatory. Thirty-five of the objects, of redshift between 0.064 and 3.53, were detected as X-ray sources. The 0.5–4.5-keV X-ray properties of these quasars are correlated with their optical and radio continuum properties and with their redshifts and variability characteristics. The X-ray luminosity of quasars tends to be highest for those objects which are bright in both the optical and radio regimes and which exhibit optically violent variability. These observations suggest that quasars should be divided into two classes on the basis of radio luminosities, spectra, evolution and underlying morphology and, thus, that quasars can make up a significant portion of the diffuse soft X-ray background only if the slope of the optical quasar log  $N$ –log  $S$  relation is steeper than 2 to  $m_B \approx 21.5$ .*

AS the most distant and luminous objects in the Universe, quasars have commanded considerable interest since their discovery nearly two decades ago. In the past few years, they have been surveyed by IR, UV, X-ray and  $\gamma$ -ray observers as well as optical and radio astronomers. X-ray emission from 3C273 was first recorded with a rocket-borne detector a decade ago<sup>1</sup>, but before the launch of HEAO 2 on 13 November 1978, only four other quasars had been detected: MR2251-178 (ref. 2), 4U0241+622 (ref. 3), NRAO 140 (ref. 4) and NRAO 530 (ref. 4).

The first results of an Einstein Observatory quasar survey<sup>5</sup>, however, make it clear that a significant new window, the soft X-ray band, has been opened for the study of these objects. Thirty-two of the 40 sources in that survey were detected in the 0.5–4.5-keV range, with luminosities from  $10^{43}$  to  $10^{47}$  erg s<sup>-1</sup>. These observations suggested that the summed contribution from the number of predicted optical quasars at faint magnitudes would exceed the diffuse soft X-ray background unless the optical quasar log  $N$ –log  $S$  relation is flattened significantly above  $m_B = 20$ , disagreeing with some optical measurements<sup>6</sup>. This surprising conclusion followed from the assumptions that: (1) the effect of the sample selection bias in favour of 'radio-bright' quasars was small, and (2) the effect of optical variability on the calculation of the X-ray-to-optical luminosity ratio could be ignored—simultaneous data at optical wavelengths were unavailable.

A second survey of quasars being carried out with the Einstein Observatory is reported here. Our sample consists of two components: a pointed survey in which 31 fields (one square degree each) containing 41 catalogued quasars were observed for an average of  $\sim 2 \times 10^3$  s, and a serendipitous survey in which each of our other  $\sim 500$  fields were examined for the presence of known quasars. The pointed survey sources were chosen to have a roughly uniform redshift distribution and to include many of the objects well studied in the radio and optical regimes. The 70 quasars in the other fields form a random collection of largely optically selected objects. Of this combined total of 111 quasars, 35 were detected as soft X-ray sources. For all of our observations, we have tried to obtain simultaneous optical measurements whenever possible but otherwise have tried to assess separately the contribution of the optically violent variables (OVVs) and to establish their optical-to-X-ray properties on the basis of nearly simultaneous measurements in the optical by A. Smith (personal communication). The initial results of this

**Fig. 1** Log of the flux at 2,500 Å (at the source) plotted against log of the flux at 2 keV (at the source). O, Objects with redshifts < 1; H, redshifts > 1; <, 3 $\sigma$  upper limits for objects. A clear positive correlation can be seen.

survey are reported, and their implications for quasar continuum emission mechanisms are considered. The significance of the revised values of X-ray brightness for the contribution of quasars to the diffuse soft X-ray background is also examined.

## Observations

All of the quasar measurements discussed in this article were obtained with the imaging proportional counter (IPC) on board the Einstein Observatory<sup>7</sup>. Thirty-five quasars met the detection criteria of a counting rate  $\geq 3\sigma$  above the background and coincidence within 80 arc s of the optical position (that is, within the 90% confidence X-ray error circle). For the stronger sources ( $>5\sigma$ ), the positional coincidences were all better than 50 arc s. The common names of the 111 quasars examined, their positional designations, their redshifts  $z$  and the times of the observations are given in Table 1.

The IPC has sufficient time resolution to permit searches for flux variations down to time scales of milliseconds. Searches for flaring activity have been conducted for the 10 sources with counting rates  $>0.05$  counts  $s^{-1}$ . No statistically significant variations ( $>3\sigma$ ) were found on time scales of 10–1,000 s. However, several of the sources have been observed more than once several months apart. In some of these cases, large ( $>100\%$ ) changes in the flux were recorded. These variability studies will be discussed elsewhere in conjunction with simultaneous observations obtained in other spectral regimes by ground-based observers.

As well as recording the arrival time and position of each photon, the IPC also provides crude spectral information. Although residual systematic uncertainties in the calibration of the IPC have so far prevented detailed analysis of the X-ray spectra, we believe that the fluxes calculated, following the

procedure suggested by Tananbaum *et al.*<sup>5</sup>, are correct to within 30%. The  $(0.5-4.5)/(1+z)$ -keV flux incident on the Galaxy,  $S_x$ , is used to calculate the 0.5–4.5-keV X-ray luminosity  $L_x$  (ref. 8):

$$L_x = S_x D \frac{4\pi c^2}{H_0^2} [z(1+0.5z)]^2 \quad (1)$$

where a Friedmann cosmology with  $H_0 = 50$  km (s Mpc) $^{-1}$  and  $q_0 = 0$  has been assumed. The logarithms of  $L_x$  and, where appropriate, the  $3\sigma$  upper limits are given in column 5 of Table 1. We compare  $S_x$  and  $L_x$  to the optical  $S_0$  and  $L_0$ , calculated for the 3,000–6,000-Å band (at the source and corrected for galactic reddening<sup>9</sup>) using *UBV* magnitudes and a common energy index of 0.7, and to the radio  $S_r$  and  $L_r$ , calculated for the 3.1–8.1-GHz band (at the source) from published 1.4-GHz fluxes and spectral indices following the prescription given by Schmidt<sup>10</sup>. Where no radio flux has been measured, upper limits corresponding to the best available limiting fluxes are used. The spectral indices  $\alpha_{ro}$ , from 5 GHz to 2,500 Å, and  $\alpha_{ox}$ , from 2,500 Å to 2 keV, can then be found from

$$\alpha_{ro} = \frac{\log [L_r/L_0]}{5.380} + 0.595 \quad (2)$$

$$\alpha_{ox} = \frac{\log [L_0/L_x]}{2.605} + 1.200 \quad (3)$$

assuming power-law behaviour within each bandpass (see Table 1).

## Data analysis

The data in Table 1 have been combined with data for 39 quasars previously discussed by Tananbaum *et al.*<sup>5</sup> (excluding their data for 3C273, MR2251-178 and 3C351, which are included in our sample), two quasars claimed by Marscher *et al.*<sup>4</sup> and 19 quasars discovered by Chanan *et al.*<sup>11</sup>. The data were then analysed for possible correlations between X-ray behaviour and quasar continuum properties in other regions of the electromagnetic spectrum. The combined sample thus comprises 171 quasars of which 87 are positive detections. Twenty-six of these quasars were first discovered through X-ray observations. Sixty-five of the combined sample have a measured 1.4-GHz flux greater than 10 mJy. Of these 'radio-bright' quasars, 11 are classified as OVV's, 9 of which are known to be active<sup>12</sup>.

A positive correlation was found between  $S_X$  and  $S_0$  for the detected quasars. Although considerable scatter is evident in the correlation diagram (see Fig. 1), the correlation coefficient of 0.67 is significant at the  $6.9\sigma$  level (using the Fisher  $z$ -statistic). Positive correlations also result from comparisons between  $S_X$  and the flux in the IR and at radio frequencies down to 15 GHz. Formally, however, there is no correlation between  $S_r$  and  $S_X$  for the sample of 65 quasars detected in both bands—the correlation coefficient is 0.04. This lack of correlation is largely attributable to three quasars: MKn205, PG0026+129 and MR2251-178. Nevertheless, Fig. 2, which is a plot of the detections and upper limits for all sources, shows a clear association between 'radio-quiet' quasars and a lack of X-ray emission. The fact that the X-ray and radio emissions are related can

**Fig. 2** Log of the flux at 5 GHz (at the source) plotted against log of the flux at 2 keV (at the source). Symbols as in Fig. 1. V, appropriate survey limiting fluxes for objects not detected in the radio. While the plot of detections forms a scatter diagram, the preponderance of X-ray upper limits corresponds to 'radio-quiet' objects in the lower left-hand corner of the diagram.

**Fig. 3** A 'colour-colour' diagram of quasars. The radio-to-optical slopes for detected quasars are plotted against the optical-to-X-ray slopes. The radio-bright objects cluster near the upper left of the diagram; the radio-quiet objects cluster near the lower right of the diagram.

be seen from a comparison of  $\alpha_{r0}$  and  $\alpha_{0x}$ . A correlation coefficient of  $-0.41$  (significant at the  $3.1\sigma$  level) was found, implying that higher radio emission leads to higher X-ray emission when both are normalized to the optical output (see Fig. 3).

Differences in the X-ray behaviour of radio quasars and optical quasars can be seen more clearly in a plot of the number of sources versus  $\alpha_{0x}$ . Figure 4 presents histograms for the 87 detected quasars segregated into: *a*, nearby radio quasars ( $z > 1$ ;  $L_r > 10^{41}$  erg s<sup>-1</sup>); *b*, distant radio quasars; *c*, nearby optical quasars ( $L_r < 10^{41}$  erg s<sup>-1</sup>, or undetected); and *d*, distant optical quasars. The total number of objects sampled in each  $\alpha_{0x}$  interval, including upper limits, are plotted as dotted histograms in the same figures. The total detected fractions along with  $\langle \alpha_{0x} \rangle$ , the mean values of  $\alpha_{0x}$ , and the standard errors of these means for the detected quasars in each of the subsamples are indicated in the figures. Clearly when the optical quasars are detected in X rays, they are detected with larger values of  $\alpha_{0x}$ . For a more quantitative analysis, a simple comparison of the measured means and their standard errors is inadequate because it does not take the upper-limit information into account. A maximum likelihood (ML) technique has therefore been applied to calculate  $\langle \alpha_{0x} \rangle$  for the total sample and for each of the subsamples.

We assume that the spectral index  $\alpha_{0x}$  is a random variate with distribution function  $f(\alpha)$  which is postulated to be independent of other quasar characteristics. Best-fit parameters are determined from the principle of maximum likelihood using standard techniques for treating censored samples and truncated distributions (see, for example, refs 13, 14). Specifically, the likelihood function to be maximized in our case is

$$L = \prod_i f(\alpha_i) \prod_j F(\beta_j) \prod_k f(\alpha_k)/F(\gamma_k) \quad (4)$$

where  $F(\beta) = \int_{\beta}^{\infty} f(\alpha) d\alpha$ . The first two factors take account of the optically selected quasars, both X-ray detected (*i*) and nondetected (*j*), and the third factor takes account of the quasars (*k*) first discovered as X-ray sources. The quantity  $\beta_j$  is the threshold on the index  $\alpha_{0x}$  of the *j*th quasar below which it would have been detected as an X-ray source. Similarly,  $\gamma_k$  is the

threshold on the index of the  $k$ th quasar below which quasar-confirming spectroscopic observations would not yet have been made. Where the optical thresholds are known (see, for example, ref. 11), we have used them. Otherwise we have adopted an arbitrary threshold one magnitude fainter than the measured quasar magnitude. For the actual data samples, changing these thresholds by  $\pm 1/2$  magnitude changes  $\langle\alpha_{0x}\rangle$  by  $<0.01$ .

A nonparametric approach following Avni *et al.*<sup>14</sup> may be used to estimate  $f(\alpha)$ . However, strict adherence to such a procedure results in  $f(\alpha)$  being identically zero outside the range of the measured values for  $\alpha$ . If, as is most likely, the present quasar samples do not span the entire range of  $\alpha$ , this unphysical cutoff will introduce a slight bias in the calculated values of  $\alpha_{\text{eff}}$ . To avoid this source of bias, we take  $f(\alpha)$  to be the normal distribution, consistent with the distribution measured for all detected quasars. The sample mean  $\langle\alpha_{0x}\rangle$  and the variance  $\sigma^2$  are then obtained by maximizing  $L$  numerically, and the standard errors of these parameters are determined in the usual way from the co-variance matrix. Monte-Carlo simulations have shown that these ML estimators are unbiased.

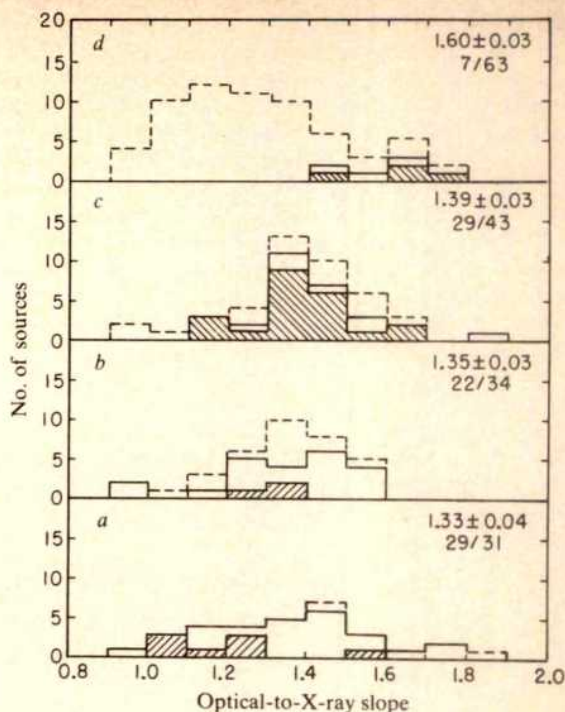

Using the above procedure, we find for the total sample of 171 quasars a value  $\langle\alpha_{0x}\rangle = 1.46 \pm 0.02$ . The 26 X-ray-selected quasars with  $\langle\alpha_{0x}\rangle = 1.41 \pm 0.03$  are indistinguishable from the remainder of the sample; they also do not differ significantly from other nearby optically selected, radio-quiet quasars (see Fig. 4c). Dividing the sample into radio quasars and optical quasars, we find values of  $1.38 \pm 0.03$  and  $1.52 \pm 0.03$ , respectively. Dividing the two classes into low- and high-redshift groups renders the distinction even more striking. Although there is no difference between the low- and high-redshift radio quasars ( $\langle\alpha_{0x}\rangle = 1.36 \pm 0.04$  and  $1.40 \pm 0.03$ , respectively), the optical quasars do show evidence of evolution with  $\langle\alpha_{0x}\rangle = 1.44 \pm 0.03$  and  $1.65 \pm 0.04$ , respectively.

Most of the difference in the values of  $\langle\alpha_{0x}\rangle$  for the two classes arises from a difference in X-ray luminosity. The luminosity distribution histograms shown in Fig. 5 suggest that, in general, optical quasars have lower X-ray luminosities than radio quasars. The mean log X-ray luminosities are  $44.61 \pm 0.16$  and  $45.64 \pm 0.13$ , respectively, for detected quasars.

We note that a subset of the radio quasars, the flat-spectrum radio sources in general and the OVV's in particular, plays a large part in establishing the distinction between radio quasars and optical quasars. The OVV's are shown as crosshatched objects in Fig. 4. For the 11 OVV's,  $\langle\alpha_{0x}\rangle = 1.25 \pm 0.05$ , compared with  $1.41 \pm 0.04$  for radio quasars without the OVV's. Discounting the OVV's, the mere absence or presence of radio emission does not strongly correlate with the level of X-ray emission from nearby objects. However, the separation at high redshifts seen in Fig. 4 remains significant.

## Discussion

The present data suggest that an instructive segregation of quasars into two types can be made: those with  $L_r < 10^{41}$  erg s<sup>-1</sup> (Type I) and those with  $L_r > 10^{41}$  erg s<sup>-1</sup> (Type II). Type I quasars make up  $\sim 90\%$  of the total population. For these objects, the typical luminosity in the 3,000–6,000-Å band

**Fig. 4** Optical-to-X-ray slope distributions for: *a*, nearby ( $z < 1$ ) radio-bright ( $L_r > 10^{41}$  erg s<sup>-1</sup>); *b*, distant radio-bright; *c*, nearby radio-quiet or undetected; and *d* distant radio-quiet or undetected quasars. The dashed histograms represent the total number of objects with a detection or a  $3\sigma$  upper limit in the appropriate  $\alpha_{0x}$  bin. The solid histogram represents only those objects which were detected in the X-ray. The hatched histograms in *a* and *b* represent the OVV's in our sample. The hatched histograms in *c* and *d* represent X-ray-discovered quasars. The total detected fraction and the mean and standard deviations for the detected quasars in each subsample are given.

ranges from  $10^{43}$  to  $10^{47}$  erg s<sup>-1</sup>. In the 0.5–4.5-keV soft X-ray regime, their output ranges from  $10^{43}$  to  $10^{46}$  erg s<sup>-1</sup> with  $\langle\alpha_{0x}\rangle \sim 1.5$  and  $\alpha_{r0} < 0.2$ . In contrast, Type II quasars are much more luminous, most notably in the radio and X-ray regimes, with  $\langle\alpha_{0x}\rangle \sim 1.35$  and  $\alpha_{r0} > 0.2$ . (If one considers the total energy radiated by several typical Type I and Type II quasars, it is clear that, though substantial overlap exists from one class to the other, Type I quasars are typically 1–2 orders of magnitude less luminous than Type II objects in the range  $10^8$ – $10^{18}$  Hz.) Our results, along with previous studies by Schmidt<sup>10</sup> and most recently by Turner<sup>15</sup>, indicate that these two types of quasars evolve quite differently: the radio-bright, flat-spectrum type II quasars are consistent with no evolution, whereas radio-quiet Type I objects exhibit a strong luminosity and/or density enhancement at earlier epochs. The parameters of the two classes are summarized in Table 2.

Data from our larger sample of active galactic nuclei provide an important clue to the underlying cause of this class distinction. N-galaxies and BL Lac objects, which are generally bright radio sources, are found to be luminous soft X-ray emitters; we find values of  $\langle\alpha_{0x}\rangle = 1.30 \pm 0.07$  and  $1.31 \pm 0.05$  for 15 and 16 observed sources, respectively. These values are consistent with  $\alpha_{0x}$  calculated for the few previously discovered BL Lacs<sup>16</sup> and N-galaxies<sup>17</sup>. A large number of these active nuclei are associated with underlying elliptical galaxies<sup>18</sup>. On the other hand, Seyfert galaxies, which are typically weak radio sources, are also found to have lower X-ray luminosities<sup>19,20</sup> and a larger  $\langle\alpha_{0x}\rangle$  when compared with nearby radio-bright active galaxies. More than 90% of Seyferts are identified with spiral or barred spiral galaxies<sup>21</sup>. This distinction in the morphology of the galaxies underlying Type I and Type II objects may signal differences in the nature of the compact nuclear source and/or its immediate environment.

**Table 2** Properties of the two quasar classes

|  | Type I                | Type II                |
|--|-----------------------|------------------------|
| % Of total population                        | 90%                   | 10%                    |
| $L_r$ (3.1–8.1 GHz) (erg s <sup>-1</sup> )   | $<10^{41}$            | $>10^{41}$             |
| $L_0$ (3,000–6,000 Å) (erg s <sup>-1</sup> ) | $10^{43}$ – $10^{47}$ | $10^{43}$ – $10^{47}$  |
| $L_x$ (0.5–4.5 keV) (erg s <sup>-1</sup> )   | $10^{43}$ – $10^{46}$ | $10^{44}$ – $10^{47}$  |
| $\langle\alpha_{0x}\rangle$                  | 1.5                   | 1.35                   |
| $\alpha_{r0}$                                | $<0.2$                | $>0.2$                 |
| Evolution                                    | Strong                | Weak                   |
| Related AGNs                                 | Seyferts              | BL Lacs,<br>N galaxies |
| Related Hubble type                          | Spirals               | Ellipticals            |
| Time variability                             | ...                   | $\times 10$ (OVV's)    |

Our observation that the X-ray flux correlates with other quasar continuum measurements from the UV region to the millimetre region, along with the observation that the mean value of the IR-optical slope of 1.3–1.4 (ref. 22) is similar to  $\langle\alpha_{\text{ox}}\rangle$ , supports the view that synchrotron radiation from a single power-law distribution of electrons is responsible for most of the  $10^{13}$ – $10^{18}$ -Hz emission in quasars. The lack of correlation between the emission at X-ray and radio frequencies may be partly due to low-frequency radio emission generally coming from a halo or extended lobe components and thus not measuring the power of the central nuclear source which is presumably responsible for all of the X-ray emission. Furthermore, the compact component may become opaque at frequencies below a few gigahertz due either to synchrotron self-absorption or to free-free absorption by intervening clouds. Absorption by such clouds can also decrease the level of measured soft X-ray emission, although very large column densities ( $n_{\text{H}} \geq 10^{23} \text{ cm}^{-2}$  at  $z = 3$ ) would be required to explain the low X-ray outputs of the high-redshift Type I objects.

Fig. 5 Histograms of the number of sources plotted against log [0.5–4.5-keV X-ray luminosity ( $\text{erg s}^{-1}$ )] for a, radio-bright objects and b, radio-quiet objects.

Although at soft X-ray energies direct synchrotron radiation seems to be dominant for nearly all quasars, a second mechanism could explain the enhanced X-ray emission from Type II objects in general and OVV in particular. Compton scattering of flat-spectrum centrimetric radio photons off relativistic electrons with a Lorenz factor of  $\sim 10^3$  can add significantly to the total X-ray emission above a few kiloelectron volts<sup>23</sup>. For the OVVs, the problem has been that the incoherent synchrotron self-Compton (SSC) process predicts high X-ray fluxes that are inconsistent with the upper limits derived from the early 2–10-keV all-sky surveys<sup>24</sup>. However, the level of X-ray emission we now observe from these sources can be made consistent with the SSC model if the emitting plasma is moving at relativistic velocities with an energy density in the electrons

comparable to that in the magnetic fields<sup>4</sup>. For the non-OVVs, the observation that there is little difference in the X-ray behaviour between the two classes for nearby quasars suggests that the Compton contribution is relatively unimportant below a few kiloelectron volts. Above a few kiloelectron volts, however, a change in spectral slope from  $\sim 1.5$  to a value  $\leq 0.5$  is expected as the dominant emission mechanism changes from synchrotron to SSC. Recent observations of the X-ray spectra of BL Lac objects<sup>25,26</sup> support the idea of spectral flattening in the 1–10-keV region. In this picture, the effective power-law index in the spectral band sampled by the IPC is  $\sim 1$  for Type II objects. As there is no  $K$  correction for a power law of index one, the lack of any distinction between  $\langle\alpha_{\text{ox}}\rangle$  at low and high redshifts for Type II objects follows directly. For Type I objects, only the synchrotron power law with  $\alpha_{\text{ox}} \sim 1.5$  is present, explaining the greater difficulty we have in detecting high-redshift Type I objects.

One important consequence of the separation of quasars into two distinct classes is that preliminary conclusions reached by Tananbaum *et al.*<sup>5</sup> concerning the contribution of quasars to the diffuse X-ray background need to be modified. Because neither the samples of quasars studied by Tananbaum *et al.*<sup>5</sup> nor by us are statistically complete, we cannot derive an X-ray luminosity function directly but must rely instead on optical quasar counts and  $L_{\text{x}}/L_0$  values for different quasars. As the surface density of quasars at faint magnitudes is generally derived from objective prism surveys sensitive to  $z > 1.7$  and as most of these sources are not strong radio sources, the proper value of  $\alpha_{\text{ox}}$  to apply to the optical quasar count is that associated with distant optical quasars. The effective  $\alpha_{\text{ox}}$ ,  $\alpha_{\text{eff}}$  (see ref. 5), inferred from the mean  $L_{\text{x}}/L_0$  ratio for all distant optical quasars, is  $1.63 \pm 0.04$ . This value means that, on average, optical quasars contribute a factor of 8 less to the diffuse X-ray background than the value of  $\alpha_{\text{eff}} = 1.27$  used by Tananbaum *et al.*<sup>5</sup>. If Type II objects comprise 10% of all quasars, their value of  $\alpha_{\text{eff}} = 1.26 \pm 0.03$  implies that they contribute  $\sim 70\%$  of the amount from all optical quasars. Treating the OVVs separately may alter the estimate, but the net result is to reduce the contribution from all quasars by a factor of  $\geq 4$  from the value given by Tananbaum *et al.*<sup>5</sup>. To explain the entire diffuse soft X-ray background as resulting from quasars, then, one must integrate the optical log  $N$ –log  $S$  relation to  $m_{\text{B}} = 21.5$  and assume that the slope of the log  $N$ –log  $S$  curve remains steeper than 2. Similar results have been reported by Zamorani *et al.*<sup>27</sup>.

We believe that the data presented here support a picture incorporating the differing importance of synchro-Compton radiation in Type I and Type II quasars, possibly enhanced to some degree by an excess of absorbing material in the radio-quiet objects. While simultaneous spectral and time variability studies over as wide a frequency range as possible are essential for further progress in this field, it is clear that X-ray observations will play a major part in our future understanding of the evolution of quasars, their connection to other active galaxies, and their precise contribution to the diffuse X-ray background.

# Cordilleran suspect terranes

Peter J. Coney

*Over 70% of the North American Cordillera is made up of 'suspect terranes'. Many of these geological provinces are certainly allochthonous to the North American continent and seem to have been swept from far reaches of the Pacific Ocean before collision and accretion into the Cordilleran margin mostly in Mesozoic to early Cenozoic time.*

RECENT tectonic studies and a new geological and geophysical data base support earlier theories<sup>1-3</sup> that much of the North American Cordillera is a vast mosaic or collage<sup>4,5</sup> of what are here termed 'suspect terranes'<sup>6</sup>. The terranes are suspect because we cannot be certain of their palaeogeographical setting with respect to North America through much of Phanerozoic time. Most are truly allochthonous and seem to have collided and accreted to the North American cratonic margin mostly during Mesozoic and early Cenozoic time<sup>7</sup>. Large-scale concurrent and post-accretionary horizontal translations of hundreds of kilometres<sup>8</sup> and significant rotations around vertical axes<sup>9,10</sup> are also indicated, both of which are continuing to the present.

## Distribution and character of terranes

The distribution of the major Cordilleran suspect terranes is shown in Fig. 1. More than 50 terranes are recognized some of which are here grouped for simplicity and designated composite terranes. Some terranes are too small to show at the scale of this map.

Once the Palaeozoic miogeocline is identified in the geology of western North America all geological terranes outside it are inherently suspect in that their palaeogeographical distribution or their palaeotectonic setting with respect to North America is uncertain. The reason is based on a simple plate tectonic concept. During most of latest Precambrian through early Palaeozoic time the western margin of North America was a passive continental margin across which was draped a growing miogeoclinal terrace<sup>11</sup> as some proto-Pacific Ocean opened. Brief periods of convergence and collision are inferred during mid-Palaeozoic time<sup>12</sup>, but the progressive out-building of the terrace was almost uninterrupted for at least 700 Myr. This regimen changed in latest Triassic to middle Jurassic time<sup>13</sup> and since then the margins of the Pacific Ocean have been convergent or transform. Subduction related to convergence consumed all of the vast Palaeozoic Pacific Ocean<sup>12</sup> and it follows that all Palaeozoic terranes now found outside the edge of the original Palaeozoic passive continental margin must have somehow accreted against that margin during Mesozoic-Cenozoic time. It also follows that all younger geological terranes outside that margin (many of which sit on older Palaeozoic rocks) are also suspect, until proved otherwise, and may have been accreted against that margin.

The terranes shown in Fig. 1 are characterized by internal homogeneity and continuity of stratigraphy, tectonic style and history. The boundaries between terranes are fundamental discontinuities in stratigraphy that cannot be explained easily by conventional facies changes or unconformity. Most boundaries separate totally distinct temporal or physical rock

sequences<sup>15,19</sup>, and many juxtapose different faunas<sup>16</sup>. Some terranes carry palaeomagnetic records that differ strongly from those of cratonic North America<sup>9,10</sup>. These data suggest large displacements and/or rotations between the terranes themselves and between the terranes and stable North America.

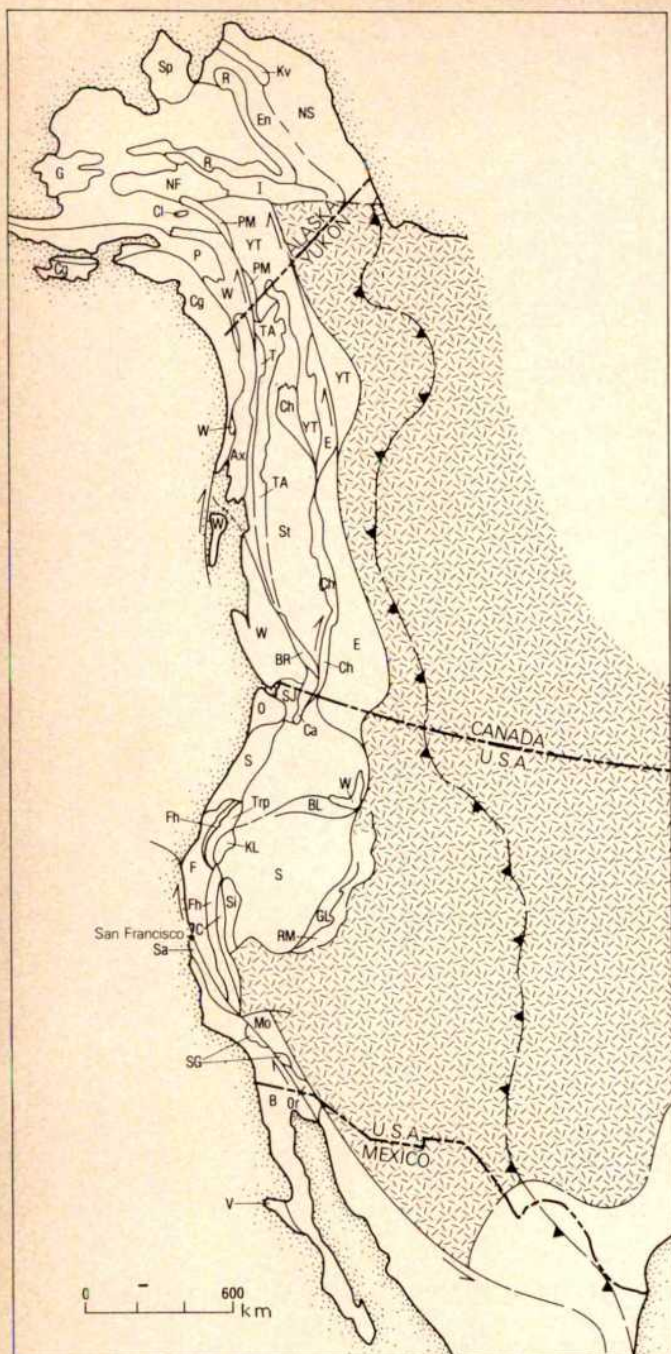

Note that identification of a terrane is based primarily on its stratigraphy<sup>14</sup> and need not carry any genetic or even plate tectonic implication. At the start of investigations, the identified terranes are simply considered as domains in the descriptive sense. Their identification and description has provided great insight into Cordilleran geological and tectonic history.

In support of the concept of terranes and their suspect character it is important that most of them display sedimentary and volcanic rock sequences that are of oceanic affinity rather than continental. It is also significant that rocks proved to be older than middle Palaeozoic are not common in the larger suspect terranes<sup>15</sup>. Most contain only upper Palaeozoic and/or Mesozoic sequences and most seem to have formed far removed from any continental influence, or at best at the most distal reaches of continental influence.

Most of the boundaries between terranes are known or suspected faults that usually display complex structural history (for example, see ref. 19). Many of the boundaries are certainly sutures, now largely cryptic, and most have been reactivated by concurrent and post-collisional large-scale, right-lateral strike-slip movements. High-pressure mineral assemblages of the blueschist facies from some of these boundaries have yielded Mesozoic radiometric ages<sup>5</sup>. Also, several boundaries are marked by thick and highly deformed Mesozoic sequences of turbidite flysch<sup>7</sup>.

The allochthonous terranes are of several types. A few are, or contain, pieces of oceanic crust (Ch, Cl, Br, SJ, BL, Trp, C) and represent last vestiges of large late Palaeozoic-early Mesozoic oceans now trapped well within the Cordillera far from the present Pacific margin<sup>15</sup>. The Permian Tethyan faunas characteristic mainly of the Cache Creek terrane are totally distinct from coeval faunas found on both sides<sup>16</sup>. Other terranes contain fragments of oceanic arcs subsequently swept against the Cordilleran margin (R, I, G, YT, W, P, St, E, Ca, BL, KL, S, Si). A significant proportion of these arcs are late Palaeozoic in age, many are late Triassic to Jurassic in age, but at least one (the Gravena-Nutzotin belt)<sup>17</sup> is as young as early Cretaceous. The major Palaeozoic and Mesozoic arcs (St, P, W) have no known basement other than presumed oceanic crust. Some of the arcs, although submarine in character, rode passenger on older basement terranes. Other terranes seem to be fragments or slices off distal parts of unknown continental edges (E, NF, PM, YT, Ax, Sa, RM) and they possess what might be termed a

**Fig. 1** Generalized map of Cordilleran Suspect Terranes. Dashed pattern, North American autochthonous cratonic basement. Barbed line, eastern limit of Cordilleran Mesozoic-Cenozoic deformation. Barbed arrows, direction of major strike-slip movements. Terranes are described below.

#### Alaska

(for further information on the distribution and character of terranes in Alaska, see refs 14, 17–20, 53)

- Sp, Seward Peninsula—structurally complex assemblage of Precambrian metamorphic and sedimentary rocks, and Palaeozoic carbonate rocks.
- NS, North Slope—Precambrian, Palaeozoic, and Mesozoic clastic and carbonate sequence—part of North America, but may have moved from original position.
- Kv, Kavik—Thin sequence of radiolarian chert, argillite, shale, and minor volcanics, Mississippian to Triassic in age.
- En, Endicott—metamorphosed Lower to Upper Palaeozoic clastic and carbonate rocks intruded by Palaeozoic granitic rocks.
- R, Ruby—composite terrane comprising at least three separate units, including Precambrian metamorphic rocks, mid to Upper Palaeozoic volcanic and sedimentary rocks, and thick piles of Lower Mesozoic basalt and chert.
- I, Innoko—structurally deformed sequence of Upper Palaeozoic to early Mesozoic chert, argillite, graywacke, and basic to intermediate volcanics.
- NF, Nixon Fork—Precambrian metamorphic rocks overlain by Palaeozoic and Mesozoic carbonate, clastic, and cherty rocks.

- G, Goodness (composite)—includes three terranes: (1) a complex assemblage of deformed Upper Palaeozoic volcanics, chert, and graywacke with blocks of older limestone; (2) Precambrian gneisses and schist; and (3) Mesozoic arc-derived volcanic flows, tuff, and graywacke, with interbedded chert.
- Cl, Chulitna (composite)—includes three terranes: (1) Devonian ophiolite overlain by Palaeozoic chert, volcanic conglomerate, limestone, and flysch, and Mesozoic limestone, redbeds, flysch, and chert; (2) Mesozoic chert, argillite, crystal tuff, and conglomeratic sandstone; (3) Upper Palaeozoic tuff, and chert, volcanic graywacke, with blocks of Lower Palaeozoic limestone.
- PM, Pingston & McKinley (composite)—includes three terranes: (1) Upper Palaeozoic phyllite and Triassic thin-bedded limestone and sooty black shale; (2) Upper Palaeozoic chert, Triassic pillow basalt, and Upper Mesozoic flysch and conglomerate; (3) Lower Palaeozoic limestone, tuff and flysch of unknown ages.
- YT, Yukon-Tanana (composite)—includes regionally metamorphosed schist and gneiss of Precambrian(?) age, Devonian limestone, Upper Palaeozoic silicic metavolcanic rocks, Permian ophiolite, and foliated granitic rocks of unknown age.
- W, Wrangellia—Upper Palaeozoic arc complex composed of flows, breccias, and volcanoclastic rocks overlain by limestone, clastics, and chert, and Mesozoic pillowed and subaerial basalt flows succeeded by limestone, cherty limestone, and clastic rocks.
- P, Peninsular—rare Palaeozoic limestone, Triassic basalt, argillite, and limestone, Lower Jurassic volcanic and volcanoclastic rocks, younger clastics.
- Cg, Chugach (composite)—includes (1) deformed Upper Mesozoic flysch and melange units, and (2) deformed Lower Cenozoic flysch and volcanic rocks.
- Ax, Alexander—complex terrane of Precambrian(?) and Palaeozoic volcanic rocks, clastics, and limestone, and Mesozoic volcanics, limestone, and clastic rocks.
- T, Taku—structurally complex assemblage of Upper Palaeozoic volcanoclastics, limestone, flysch(?), and Lower Mesozoic basalt, limestone, and flysch.
- TA, Tracy Arm—structurally complex assemblage of marble, pelitic gneisses, and schist of unknown ages.

#### Canada

(for further information on distribution and character of terranes in Canada, see refs 2, 5, 8, 15, 16, 19, 25, 33)

- Ch, Cache Creek terrane—Mississippian to Middle (Upper?) Triassic, highly disrupted radiolarian chert, argillite, basalt, alpine-type ultramafics, large shallow-water carbonates, and local blueschist metamorphism.
- BR, Bridge River terrane—Middle Triassic to Lower Middle Jurassic, highly disrupted radiolarian chert, argillite, basalt, alpine-type ultramafics and minor carbonate.
- St, Stikine terrane—Mississippian and Permian volcanoclastics, basic to acidic volcanics and carbonates, locally deformed and intruded in middle to late Triassic time, overlain by Upper Triassic to Middle Jurassic volcanogenic strata.
- E, Eastern assemblage (composite)—includes possible late Precambrian-early Palaeozoic metamorphic terranes, of possible continental affinity, together with Mississippian to Triassic basalt, ultramafics and chert and volcanoclastics and carbonates, overlain unconformably by Middle Triassic to Lower Jurassic volcanogenic strata.

#### Washington and Oregon

- SJ, San Juan (composite)—includes highly deformed Mesozoic chert, argillite, graywacke, and volcanic rocks, partly in melanges, with blocks of lower Palaeozoic plutonic rocks, Palaeozoic chert, carbonates, and volcanic rocks. Permian limestone blocks contain Tethyan fusulinids (see ref. 54).
- Ca, Northern Cascades (composite)—includes crystalline and pelitic gneisses, and thrust sheets composed of (1) Upper Palaeozoic andesitic volcanics and associated sedimentary rocks; (2) green schist and blue schist; and (3) Jurassic ophiolite (see ref. 55).
- O, Olympic—Lower Cenozoic volcanic rocks and associated deep and shallow water sedimentary rocks. Basement unknown, but presumed to be oceanic (see ref. 56).
- S, Lower Cenozoic volcanic and sedimentary rocks lying west of the Cascade Range. Palaeomagnetic data imply post-Eocene clockwise rotation of 70° (see refs 35, 36).
- BL, Blue Mountains (composite)—includes melange with blocks of Palaeozoic ophiolite, limestone, and chert, and Mesozoic chert and sandstone, structurally overlain by Triassic and Jurassic volcanic sandstone, conglomerate, and argillite (see refs 57, 58).

#### California

- Fh, Foothills—Upper Jurassic andesitic volcanic and volcanoclastic rocks associated with phyllite, slate, and graywacke, and Upper Jurassic ophiolite (see refs 59, 60).
- Trp, Triassic and Palaeozoic of Klamath Mountains (composite)—includes a structurally complex assemblage of Lower Mesozoic ophiolite, chert, basalt, Jurassic andesitic rocks, and associated sedimentary rocks (see refs 61, 62).
- KL, Eastern Klamath Mountains—Middle to Upper Palaeozoic clastic, volcanic, and carbonate rocks, overlain by Triassic and Jurassic volcanics and minor limestone (see refs 63, 64).

- Si, Northern Sierra—Lower Palaeozoic clastic sedimentary rocks, Upper Palaeozoic and Lower Mesozoic volcanic and associated sedimentary rocks (see ref. 65).
- C, Calaveras (composite)—including a western belt of melange with ophiolite and Mesozoic chert, and an eastern belt of quartzose clastic rocks, argillite, and minor Permian limestone (see ref. 66).
- F, Franciscan (composite)—includes Upper Mesozoic Great Valley sequence with ophiolite at base, and structurally underlying disrupted and partially metamorphosed rocks of the Franciscan Complex (see ref. 67).
- Sa, Salinia—includes metamorphosed pelitic rocks, marble, and graywacke of unknown ages, intruded by Cretaceous granite plutons (see ref. 68).
- SG, San Gabriel (composite)—two structurally complex and juxtaposed Precambrian crystalline terranes intruded by Mesozoic plutons (see ref. 69).
- OR, Orocopia—metagraywacke and mudstone and minor chert and basic volcanic rocks, age unknown. No known basement (see ref. 70).
- Mo, Mohave (composite)—juxtaposed and disrupted Palaeozoic sedimentary sequences, Lower Mesozoic sedimentary and volcanic rocks intruded by Mesozoic plutons (see ref. 71).

#### Mexico

- B, Baja—includes scattered localities of Upper Palaeozoic limestone and Lower Mesozoic clastic rocks, overlain by a thick pile of Upper Mesozoic volcanic and volcanoclastic rocks, capped by latest Cretaceous quartzofeldspathic sandstone (see ref. 72).
- V, Vizcaino (composite)—includes Triassic basalt, chert, and limestone, Upper Jurassic arc-derived volcanic and volcanoclastic rocks, Upper Jurassic and Cretaceous clastic rocks, ophiolite, and structurally underlying Upper Mesozoic blue schist and disrupted rocks similar to the Franciscan Complex (see ref. 73).

#### Nevada

- S, Sonoma (composite)—includes Upper Palaeozoic volcanics in the south, and Lower Mesozoic volcanics in the north. Si and KL terranes originally included in Sonoma (see ref. 74).
- GL, Golconda—structurally deformed assemblage of chert, argillite, minor limestone, and volcanics of Mississippian to Permian age (see ref. 75).
- RM, Roberts Mountains—structurally complex assemblage of chert, argillite, sandstone, basalt, and minor limestone of Cambrian to latest Devonian or early Mississippian ages (see ref. 76).

'quasi-continental' character. A few terranes are of uncertain origin. A significant number of the terranes have basalt or gabbroic rocks, particularly of late Triassic age (I, PM, W and so on) suggesting they are fragments from rifting events, intraplate volcanism, or oceanic plateaus of unknown origin or setting<sup>18</sup>.

In a few cases it can be shown by stratigraphical and structural controls that disparate terranes amalgamated before final accretion against the North American margin<sup>18,19</sup>. One of the largest and best documented cases is the amalgamation of Wrangellia<sup>20</sup> with the Alexander terrane. Wrangellia everywhere comprises a late Palaeozoic submarine arc assemblage, with no known basement, overlain by a distinctive and very thick (up to 6,000 m) partly submarine, partly subaerial Upper Triassic basalt, overlain in turn by sedimentary rocks which extend into the early Jurassic. Palaeomagnetic data from identical Upper Triassic basalt sequences in eastern Oregon (J. Hillhouse, personal communication), Vancouver Island in western Canada<sup>21</sup>, and from southern Alaska<sup>22</sup> all record the same low Triassic palaeolatitudes with respect to Triassic North America. The Alexander terrane is a complex assemblage of volcanosedimentary rocks of Palaeozoic age<sup>17</sup>. Somewhere on route from its equatorial origins, Wrangellia amalgamated with the Alexander terrane<sup>3,19</sup>, as demonstrated by the overlapping Upper Jurassic and Cretaceous strata of the Gravina-Nutzotin belt, and with the Lower Jurassic arc of the Peninsular terrane<sup>18</sup>. Once amalgamated the resulting super-terranes was the site of variably distributed Jurassic to Lower Cretaceous Gravina-Nutzotin<sup>17</sup> arc activity before its final consolidation into the Cordilleran orogen. Since accretion Wrangellia has been fragmented by major horizontal translations and rotations so that its pieces are now scattered over almost 2,000 km of the Cordilleran margin from Oregon to Alaska<sup>20</sup>.

Some terranes are very small (most are not shown on Fig. 1) and have no known counterparts in the Cordillera. A remarkable example is in the Chulitna terrane<sup>23</sup> in southern Alaska. It lies with other small, but totally distinct, terranes embedded in a mass of late Jurassic to early Cretaceous flysch north of the Wrangellia terrane in the Central Alaska Range. Only several

tens of kilometres long, the terrane is a nappe-like structure exposing in continuous sequence late Devonian ophiolite, Mississippian chert, Permian volcanic conglomerate and breccia, flysch, chert and limestone, Lower Triassic limestone, Upper Triassic red beds and basaltic to silicic volcanics, Jurassic sandstone and chert, and Cretaceous argillite, chert, sandstone and coquinooid limestone. No other stratigraphic section such as this is known anywhere in the Cordillera. Lower Triassic ammonites from this terrane are of equatorial affinity<sup>24</sup> and indicate a southern origin.

Not shown in Fig. 1 are some overlap assemblages termed superjacent terranes. These terranes are sedimentary and volcanic sequences deposited on the basement terranes shown in Fig. 1 and tie together previously disjunct terranes. The Gravina-Nutzotin belt<sup>17</sup> is an example. Analyses utilizing basement and superjacent stratigraphy, biostratigraphy and palaeomagnetic data combined with consideration of belts of dated cross-cutting plutonic rocks provide critical data for unraveling the pre-, syn-, and post-accretionary history of these complex structural units.

### Accretionary history

A full understanding of the history of accretion and post-accretionary consolidation of Cordilleran suspect terranes into the North American Cordillera is incomplete. Although we review here what is known or suspected for the assembly as a whole, much of what we say is preliminary as additional complexities continue to unfold.

Southern Alaska is made up of several large terranes with numerous smaller ones scattered along the margins and between the larger ones<sup>18,23</sup>. The Yukon-Tanana terrane is largely made up of heterogeneous gneiss and schist, scattered deformed plutons, and high-level sheets of chert, basalt and ultramafic rock. The terrane is probably composite with nappes of upper Palaeozoic oceanic assemblages thrust across a quartzofeldspathic and silicic volcanic-rich protolith of probable Precambrian to known Palaeozoic age and of unknown continental affinity. The time of final emplacement of the composite terrane against North America is not known, but may have been as recent as Cretaceous time with earlier amalgamation in the Triassic<sup>25</sup>. Subsequently, in post-Early Cretaceous time Wrangellia, already amalgamated with the Lower Jurassic Peninsular arc terrane and Alexander terrane, collided with the Yukon-Tanana terrane entrapping many smaller terranes of unknown origin (including Chulitna terrane) within a flysch-filled suture zone<sup>18,26</sup>. The successive accretions must have caused subduction systems to step southward and from late Cretaceous to early Tertiary time, the Chugach and younger accretionary flysch prisms were emplaced against the newly formed North American margin<sup>27</sup>. Concurrent and post-accretionary convergence has caused translation and intra-plate deformation with reactivation of old sutures. This has resulted in northwestward strike-slip displacements of hundreds of kilometres along the Tintina, Denali and other faults in Alaska and adjacent Canada<sup>25,28-30</sup>.

The largest allochthonous terrane in Canada is the Stikine terrane<sup>15</sup>. It has a basement of upper Palaeozoic submarine arc rocks overlain by Upper Triassic to Middle Jurassic submarine and subaerial volcanic and sedimentary rocks (Takla-Hazleton assemblage)<sup>15</sup> and intruded by coeval granitic plutons. This major block seems to have accreted between early Triassic and mid-Jurassic time<sup>25,31</sup> entrapping between itself and the North American margin Tethyan ocean floor (Ch) and a collage of Palaeozoic 'oceanic' arcs and possible distal fragments of the Cordilleran continental terrace (E). The late Jurassic and Cretaceous Bowser Basin<sup>32</sup> overlap assemblage is deposited on Stikine terrane and records the first clear sediment source to the east, of both continental and oceanic (Ch) character. Final stages of the accretionary process were emplacements of nappes eastwards and westwards from the suture zone and on to the former continental margin. This eastern accretion was followed by the arrival of Wrangellia<sup>7</sup>, which, from Vancouver Island north,

seems to have been in middle Cretaceous time. In eastern Oregon, its arrival time may be earlier. The northern part of Wrangellia had already amalgamated with the Alexander terrane, as explained above, and arrived bearing a Jurassic arc and the Gravina–Nutzotin late Jurassic to early Cretaceous submarine arc terrane on it. Subsequent thrusting and northward translation on intra-plate strike-slip faults<sup>8,33</sup> largely during late Cretaceous to early Tertiary time, have disrupted the original relationships, but left a detached fragment of Wrangellia isolated in eastern Oregon. Once again, subduction zones must have stepped outboard through successive accretions, for by late Cretaceous–early Tertiary time the trench was on or near the present Pacific margin<sup>8</sup>.

Much of the central western part of the Cordillera in the US is underlain by several terranes (S, BL, KL, Si, Trp, C) whose very poorly exposed relationships to one another are still imperfectly understood<sup>34</sup>. Certainly the Permian Tethyan fauna-bearing terranes of Oregon and California are important and which move to positions much closer to the Pacific margin as they are tracked southward from their more internal position in Canada. No Tethyan fauna-bearing terranes are known south of central California. The Roberts Mountain allochthon of west-central Nevada is probably a distal continental terrace or marginal oceanic assemblage emplaced across the Cordilleran miogeocline in middle Palaeozoic time<sup>12</sup>. This is the oldest known example of accretion in western North America. Most of the remaining suspect terranes in the northern Sierra Nevada, Klamath Mountains and western Nevada are Palaeozoic to Mesozoic volcanic and sedimentary sequences of oceanic and arc-trench affinity which were swept against the Cordilleran margin in late Palaeozoic to middle Mesozoic time<sup>7</sup>. By mid-Cretaceous time the Franciscan accretionary assemblage was forming on the outboard margin of North America. Siletzia, a submarine basalt province of early Tertiary age in western Oregon certainly rotated clockwise over 70° since Eocene time<sup>35,36</sup> and was only finally emplaced in mid-Tertiary time.

In southwestern North American Precambrian basement extends nearly to the present coastline in southern California and northwestern Mexico. This precludes major large accretionary masses there, but several smaller displaced terranes (Sa, SG, Or) of both oceanic and quasi-continental character are known along this margin. Another important relationship is that some Jurassic magmatic arc terranes were intruded into, or deposited on, North American cratonic basement in northwestern Mexico and the southwestern US. This is in direct contrast to arcs of similar age north of central California which are ubiquitously found outside confirmed North American basement and intruded into or deposited on the suspect terranes themselves. As stated earlier, this makes the northern Mesozoic arc terranes as suspect as the terranes they sit on until it is proved otherwise. How all these Upper Triassic to Jurassic arcs relate to one another along strike and which way they faced are problems currently under much discussion and investigation. Note that major low-angle thrusting in southern California and southwestern Arizona is emerging from recent work and large-scale emplacement of allochthons in this region is not precluded<sup>37,38</sup>.

The major displaced terrane in southwestern North America so far proposed is of totally different character from those described northwards in the Cordillera. This terrane is that part of the North American craton which is supposed to have moved up to 800 km southeastwards relative to stable North America along the Mojave–Sonora megashear<sup>39</sup> or transform fault. This movement is said to have taken place in late Jurassic time and was kinematically linked to the opening of the Atlantic Ocean and the Gulf of Mexico as Africa–South America separated from North America.

## Conclusions

The collisions and accretions in western North America discussed above have profound implications for Cordilleran tecto-

genesis<sup>25,40</sup>. The mechanical process of these accretions and their effect on the accreted masses themselves and on the Cordilleran margin are poorly understood. Certainly thrust faulting has played a dominant part and if the thrust faulting within the accreted terranes is linked to the thrust belts<sup>41,42</sup> along the eastern Cordilleran margin as has been suggested<sup>25</sup>, the resulting telescoping is unprecedented in Cordilleran tectonic thought. Concurrent and post-accretionary telescoping, and consolidation apparently took place by major intra-plate thrusting and strike-slip translations<sup>25</sup>. The entire process seems to have endured over a period of at least 120 Myr or from mid-Jurassic well into early Tertiary time. Much northward translation and clockwise rotation occurred which suggest oblique convergence from a general northward Pacific 'mega-drift'<sup>7</sup>, as implied by palaeomagnetic data.

The analogy with the Himalayan orogen and the internal disruption of Asia<sup>43</sup> is striking, but there are major differences. Unlike India, a large continental mass which remains coupled to the Indian Ocean plate as the subcontinent indents Asia, the comparatively smaller accreted terranes in western North America became uncoupled from Pacific Ocean plates by formation of subduction zones near the present Pacific margin in late Mesozoic time. Much of the telescoping and translation continued inside the marginal subduction zones well into Tertiary time. During the late Cretaceous to early Tertiary period of Laramide deformation<sup>6</sup> possible elevated convergence rates between North America and the Farallon and Kula plates combined with variably dipping subducting slabs<sup>44</sup> may have produced deep-seated Laramide tectonism and complex shifting magmatic patterns across the Cordilleran foreland as a final stage to consolidation of the Cordilleran mosaic and its cratonic foreland. Also North America's generally northwestward and westward motion over the mantle against the generally northward-moving accretions may have been dynamically important<sup>41,42,45</sup>. It is not accidental that Cordilleran telescoping on the foreland only began after the Middle Jurassic initiation of opening of the Central Atlantic Ocean which sent the North American plate northwestward then westward over the Pacific Ocean<sup>41,8</sup>. Post-middle Tertiary successive overriding of Pacific spreading centres by North America has produced the complex transform regimen which has affected North America's western edge down to the present<sup>46</sup>.

The numerous upper Palaeozoic and lower to middle Mesozoic arcs that so characterize the allochthonous terranes are of special interest. None of these can be confirmed to have stood on the North American cratonic margin. They may have stood offshore in the manner of the present western Pacific Ocean arcs, but if they did we still do not know which way they faced. In any event they would have to have eventually collapsed against the North American margin by subduction of various sorts of small ocean basins caught behind them. This view is attractive because of the example of the western Pacific Ocean, but it does present some difficulties. The principal difficulties are the scraps of Tethyan ocean floor caught inside these arcs and preliminary palaeomagnetic evidence<sup>9,10,47,48</sup> which suggest large northwards translations of some of these arcs before final accretion. All this presents the possibility that the arcs may indeed be far travelled and totally unrelated to North America and thus exotic fragments from far reaches of the Pacific Ocean<sup>7</sup>. It is not until Cretaceous time that a semi-continuous magmatic arc along the Cordilleran margin can be substantiated by plutonic, volcanic and stratigraphical data<sup>6,52</sup>.

Either of these models is consistent with possible plate palaeogeographies of the time. During late Palaeozoic and early Mesozoic time two-thirds of our planet's surface was paved with a single enormous ocean<sup>49</sup>. The other third was Pangea. Assuming that lengths and spacings of spreading centres were similar then to that now, a single large ocean would statistically favour more percentage area of old ocean crust lying around ready to be subducted than at any other time before or since the Phanerozoic. If offshore and/or intra-oceanic arcs correlate with subduction of cold and dense old oceanic crust, as has been

suggested<sup>50</sup>, large parts of the late Palaeozoic-early Mesozoic palaeo-Pacific Ocean could have been festooned with magmatic arcs<sup>51</sup>. As Pangea began to break up and North America began to advance over that Ocean, the arcs could have been swept northwards against large sectors of North America's margin to

produce much of the Cordilleran mosaic which has been considered here. During this process, the Pacific was cleared of older arcs, oceanic plateaus and continental fragments, leading thus to the creation of the simple plate configuration that characterizes the present eastern Pacific.

# Voltage-dependent translocation of the asialoglycoprotein receptor across lipid membranes

Robert Blumenthal, Richard D. Klausner & John N. Weinstein

Section on Membrane Structure and Function, LTB, DCBD, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205

*A membrane receptor protein for asialoglycoproteins induces voltage-dependent increases in ion conductance across a lipid bilayer, probably reflecting penetration of the protein into the bilayer towards an electrically positive pole. In the presence of specific ligand for the receptor, this penetration leads to a 'translocation' of the receptor from one side of the bilayer to the other. These observations suggest a mechanism by which biological membranes might regulate the disposition of their proteins, and a way in which membrane receptors involved in endocytosis might be spared lysosomal destruction in order to be recycled to the plasma membrane.*

BOTH the lipid and the protein components of biological membranes seem to be asymmetrically distributed<sup>1</sup>. A key question is whether the biosynthetic process determines once

and for all the orientation of a given membrane component, or whether later processes can affect the component's disposition. At least some membrane lipids do seem to redistribute between

the inner and outer leaflets of the bilayer in a relatively rapid process whose nature is at present not clear<sup>2</sup>. We show here that a membrane receptor protein for asialoglycoproteins induces voltage-dependent increases in ion conductance across a lipid bilayer, probably reflecting penetration of the protein into the bilayer towards an electrically positive pole. In the presence of specific ligand for the receptor, this penetration leads to a 'translocation' of the receptor from one side of the bilayer to the other. These observations suggest that the membrane potential might have a role in regulation of the disposition and function of membrane proteins.

To investigate the assembly and disposition of proteins in membranes we have studied the interaction with lipid bilayers of a membrane receptor purified from rabbit hepatocytes. This hepatic binding protein (HBP) has been studied extensively<sup>3</sup>. When serum glycoproteins are desialylated to expose penultimate galactose moieties, they are removed from circulation by binding to this receptor, with subsequent endocytosis.

A general outline of receptor-mediated endocytosis is the following. After the ligand has bound to the receptor it is rapidly endocytosed and delivered to a lysosome, where it is degraded. The process has a half life of 15–60 min. The receptor, on the other hand, has a half life of ~88 h (ref. 4). This raises a topological problem: the receptor's binding sites face outwards from the plasma membrane. After ligand binding and endocytosis, they would be expected to face the inside of the lysosome and to be destroyed. However, evidence<sup>4</sup> suggests that the receptor in fact faces the outer, cytosolic surface of vesicles in the lysosome-enriched fraction. Thus the receptor may cross the membrane at some point during endocytosis, and we present here a possible mechanism for such a translocation.

Rabbit HBP can be purified to homogeneity and, as shown by SDS polyacrylamide gel electrophoresis, has two subunits, of molecular weights 40,000 and 48,000 (ref. 5). By precipitation with ethanol it can be obtained in water-soluble form, free of detergent and of bilayer lipid. Our previous studies<sup>6</sup> showed that this protein forms a stable association with phosphatidylcholine vesicles merely by mixing of the protein with vesicles. Here we report the interaction of HBP with black lipid membranes (BLMs). Advantages of the BLM were the accessibility of both sides of the membrane for addition of reagents and the ease with which the membrane potential could be controlled. Partial insertion of a protein into a BLM can perturb the membrane's structure and increase the permeation of ions across it (that is, increase its conductance)<sup>7</sup>.

## The nature of HBP-induced BLM conductance

Figure 1 shows an asymmetrical conductance increase seen when HBP was added to one side (*cis*) of a BLM. When the potential was negative on the *trans* side, the conductance was that of an unmodified BLM. When the potential was positive on the *trans* side, HBP induced a conductance increase to about 10 times that of the unmodified BLM. In most such experiments the conductance changed to 10–100-fold the unmodified BLM level (see below). Conductance changed in the form of rapid fluctuations rather than in the discrete, uniform steps characteristic of channels or the fast, smooth rise characteristic of carriers<sup>8</sup>. This form suggests that the conductance was induced by a perturbation of membrane structure<sup>7</sup> rather than by an ionophore associated with HBP. Figure 1 shows the asymmetrical time dependence and voltage dependence of the conductance increase. In Fig. 1a the voltage was switched at time intervals of about 30 s between +60 and –60 mV. During *trans*-positive intervals the conductance increased, and during *trans*-negative periods it decreased. The time required for conductance increase was much longer than that for the decrease. When the voltage was imposed in the form of a triangular wave (Fig. 1b), the result suggested a threshold effect; that is, the conductance started to rise steeply as the voltage increased and then decreased sharply as the voltage fell below 20–30 mV *trans*-positive. With a *trans*-positive voltage above threshold the conductance increased with time (Fig. 2). If the voltage was held below threshold a low conductance could be maintained for hours.

The diffusion potential of an HBP-modified BLM, measured as a function of potassium nitrate concentration ratio, showed a slope of about 10 mV per decade of concentration ratio  $[K^+]_{cis}/[K^+]_{trans}$ , indicating a slight selectivity for cations over anions.

The suggestion from the BLM experiment (Fig. 1) that HBP moves towards a *trans*-positive potential was supported by studies of HBP inserted into phospholipid vesicles by methods described elsewhere<sup>6</sup>. We determined the exposure of the protein's tryptophan groups to aqueous quenchers, iodide and acrylamide. The fluorescence intensity of the tryptophan residues in vesicle-associated HBP decreased with increasing concentration of quencher. When we imposed a *trans*-positive voltage gradient across the vesicles by adding the  $K^+$ -selective ionophore valinomycin in the presence of a  $K^+$  gradient, the quenching was markedly reduced, suggesting a voltage-

**Fig. 1** Asymmetric conductances in a HBP-modified BLM. The BLM was formed from a solution of oxidized cholesterol (2% in *n*-decane) applied across an aperture (1-mm diameter) in a Teflon partition separating two 3-ml chambers, according to the procedure developed by Mueller and Rudin<sup>24</sup>. Each chamber contained an aqueous solution of KCl (6 mM), NaCl (139 mM), and HEPES (10 mM) at pH 7.4. The solution contained about 50  $\mu$ M  $Ca^{2+}$ . HBP (final concentration 10  $\mu$ g ml<sup>-1</sup>) was added to one compartment (*cis*) and the solution was stirred by means of Teflon-covered magnets turned by a d.c. motor fixed below the bilayer chamber. The records were taken immediately after adding the HBP. The initial conductance was 0.1 nS. The area of the BLM was  $8 \times 10^{-3}$  cm<sup>2</sup>. The voltage was applied from a d.c. battery switched at arbitrary times by hand (a) or in the form of a triangular wave at a frequency of 0.003 Hz using a function generator (Hewlett-Packard 3310B) (b). Current was passed through the BLM by means of Ag/AgCl electrodes and fed into a current transducer that converted membrane current (I) into a voltage signal. The output of the voltage source and of the current transducer were fed into two channels of a d.c. recorder (Leeds and Northrup 624). The voltage is defined as  $\psi_{trans} - \psi_{cis}$ . Note that in Fig. 2b there is a small capacitive current.

**Fig. 2** Symmetrization of conductance on addition of specific ligand or  $\text{Ca}^{2+}$  to an HBP-modified BLM. The conditions were as described in the legend to Fig. 1. Voltage (not shown) was applied in a rectangular wave form alternating between +50 and -50 mV, at a frequency of 0.04 Hz. *a*, The same buffer as in Fig. 1; *b*,  $10 \mu\text{g ml}^{-1}$  ASOR added to the *cis* side; *c*, 2 mM  $\text{Ca}^{2+}$  present on both sides.

**Fig. 3** The effect of pronase on the current through an HBP-ASOR-modified BLM. HBP and ASOR were added to the *cis* side. The conditions were as described in Fig. 2b legend.  $100 \mu\text{g ml}^{-1}$  *Staphylococcus aureus* (Sigma) protease (equivalent to pronase) was added to the *cis* chamber (*a*) or to the *trans* chamber (*b*).

dependent penetration of the HBP into the vesicle bilayer. Valinomycin, in the presence of  $K^+$  but without a  $K^+$  gradient, had no effect on quenching.

### The effects of ligand and $Ca^{2+}$

Figure 2 shows the pattern of conductance change induced in the BLM by HBP in the presence of the ligand asialo-orosomucoid (ASOR) and in the presence of  $Ca^{2+}$ . In each case the reagents were added to the *cis* side only. ASOR alone did not affect BLM conductance. With HBP alone (Fig. 2a), the conductance remained asymmetric, but it became symmetrical and increased rapidly when ASOR was added (Fig. 2b). To test the specificity of this effect, the terminal galactose residues of ASOR were removed by enzymatic hydrolysis with  $\beta$ -galactosidase. In accordance with the known specificity of the binding protein, the resulting product, agalacto-orosomucoid, failed to increase or symmetrize the conductance of an HBP-modified BLM.

In the presence of 2 mM  $Ca^{2+}$  (Fig. 2c) the conductance symmetrized, but the rate of conductance increase was relatively slow.  $Mg^{2+}$  had no effect. When ASOR (see Fig. 4) or  $Ca^{2+}$  (not shown) was added to the *trans* side of an asymmetrically conducting HBP-modified BLM, there was no effect on conductance and no symmetrization. As expected, addition of HBP alone to both sides of the BLM induced a symmetrical conductance (not shown). The simplest interpretation of the symmetrization seen with HBP and either ASOR or  $Ca^{2+}$  (Fig. 2) is movement of (part of) the HBP to the opposite side of the membrane.

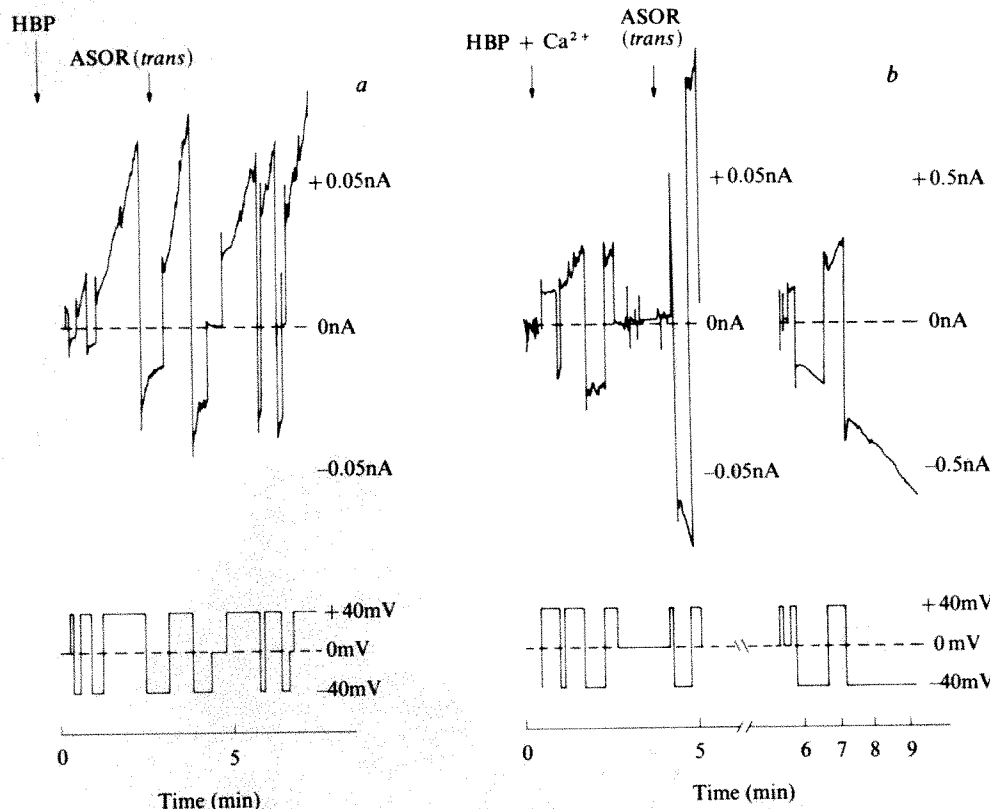

### Evidence for translocation of HBP across the membrane

We tested this notion of membrane crossing or 'translocation' by adding pronase to the *cis* side of an asymmetrically conducting BLM. This abolished the conductance increase, indicating degradation of HBP on that side; pronase had no effect when

added to the *trans* side. However, after conductance had been symmetrized by addition of HBP and ligand to a BLM, addition of pronase to the *cis* side resulted in an asymmetric conductance of the polarity corresponding to addition of HBP to the *trans* side of the membrane only (Fig. 3a). Thus with a *trans*-positive potential the conductance decreased. With a *trans*-negative potential the conductance initially increased, indicating that the HBP had entered a conducting state on the *trans* side. With prolonged exposure to *trans*-negative potential, all conductance eventually disappeared (not shown). This finding is consistent with a gradual potential-induced translocation of HBP back to the *cis* side, where it could be degraded by pronase. On the other hand, when the potential was maintained *trans*-positive, the protein was not degraded, and the new asymmetry could be maintained (not shown), indicating that pronase had not crossed the BLM.

When pronase was added to the *trans* side of a symmetrically conducting BLM (Fig. 3b), the pattern of conductance change was complicated but consistent with translocation of the conducting moiety of HBP. When the potential was made *trans*-negative, there was a decrease in conductance consistent with transition of HBP to a non-conducting state on the *trans* side and an inability to recruit conducting moieties from the *trans* side because those had been degraded by pronase. When the voltage was switched to *trans*-positive there was a transient increase in conductance due to transition of HBP into a conducting state, followed by a conductance decrease due to exposure of HBP which had apparently crossed over towards the pronase on the *trans* side. The conductance eventually disappeared when the potential was held *trans*-positive for longer times. Adding new HBP and ASOR to the *cis* side resulted in a repetition of the pattern.

Figure 4 suggests that a binding moiety of HBP is translocated. With HBP on the *cis* side, ligand had no effect when added to the *trans* side (Fig. 4a); when added to the *cis* side it increased and symmetrized the conductance (Fig. 2b). However,

**Fig. 4** Effect of adding ligand to the '*cis* and *trans*' sides. The conditions were as described in Fig. 1 legend. *a*,  $10 \mu\text{g ml}^{-1}$  ASOR added to the *trans* side at about 2 min; *b*, 2 mM  $Ca^{2+}$  present on both sides and  $10 \mu\text{g ml}^{-1}$  ASOR added to the *cis* side at ~3 min.

when a symmetrical conductance was induced in the presence of 2 mM  $\text{Ca}^{2+}$ , the conductance further increased markedly and symmetrically when ligand was added to the *trans* side (Fig. 4b). Again this was specific for the ligand; agalacto-orosomucoid had no effect on the conductance.

Figure 5 shows the absolute dependence of a conductance increase and subsequent symmetrization on the *trans*-positive potential. In the presence of HBP and ASOR a *trans*-negative voltage of 50 mV was applied across the BLM for 60 min giving no conductance change. When the voltage was then switched to a *trans*-positive polarity, the conductance started to increase and became symmetrical.

## Discussion

Figure 6 shows a hypothetical view of the interaction between HBP and lipid bilayers. The protein first associates with the bilayer without requiring a membrane potential (a). Our previous studies<sup>6</sup> have shown this to be hydrophobic interaction involving perturbation of the lipid bilayer and a conformational change in the HBP. Under the influence of a *trans*-positive membrane potential the protein can be promoted reversibly into a conducting state (b) in which it seems to perturb the bilayer sufficiently to permit passage of ions, that is, to increase the conductance of the membrane. The polarity of this effect makes sense, as HBP is negatively charged (isoelectric point at pH 4.7). The increase in conductance does not have the characteristics of a well defined channel or carrier. It does correlate, however, with the finding in lipid vesicles that HBP tryptophans become markedly less accessible to fluorescence quenchers in the aqueous phase when valinomycin and a  $\text{K}^+$  gradient are used to generate a *trans*-positive potential. The conductance increase and the tryptophan sequestration suggest a further penetration by the protein, perhaps sufficient to perturb the second leaflet of the bilayer. However, these observations could also be accounted for by an aggregation, or by a combination of penetration and aggregation such as that in Fig. 6b. Analogously, Shinitzky has considered that vertical displacement of membrane proteins could be mediated by changes in lipid packing<sup>9</sup>.

The next stage (Fig. 6b, c) is a translocation of the protein from the *cis* to the *trans* side of the membrane under the influence of a *trans*-positive electric field in the presence of a galactose-terminal ligand or  $\text{Ca}^{2+}$ . Observations supporting translocation are (1) that the membrane conductance becomes symmetrical, (2) that part of the HBP becomes exposed on the *trans* side and is destroyed by pronase there, and (3) that ligand

Fig. 5 Requirement of *trans*-positive potential for translocation of HBP across a BLM. The conditions were as described in Fig. 2b legend.

Fig. 6 Model for the translocation of the receptor protein (see text for explanation). The schematic rendering of two protein molecules is meant to suggest possible protein-protein interaction, not necessarily dimeric.

binding sites also become exposed on the *trans* side, where they are available for binding and cause a further increase in conductance. We do not know whether a given binding site exposed on the *cis* side becomes exposed on the *trans* side or whether an initially buried site is simply pushed through to the other side. Furthermore, we cannot say whether the protein actually flips over.

Two protein molecules are shown in Fig. 6 to indicate the possibility that protein-protein interaction is important in the translocation. It would provide an alternative to the energetically improbable movement of hydrophilic and charged residues directly through the low dielectric bilayer interior. Thus, charge delocalization and neutralization, by apposition of charged residues (either within a molecule of HBP or by aggregation as shown), could drastically lower the barrier. A possible role for  $\text{Ca}^{2+}$  in charge neutralization is suggested by the symmetrization seen in Fig. 2c.

Despite the topological problem outlined earlier, biochemical data suggest that the binding sites of HBP are on the cytosolic surface in the lysosomal fraction, and that they survive, presumably to be recycled to the plasma membrane. Although one must be cautious about the correspondence<sup>10</sup> between biological membranes and a model system such as the BLM, our observations do provide a conceptual basis for the translocation that may be required. The hepatic cells are inside-negative<sup>11</sup>, and the receptor is directed outward; measurements of ion distribution suggest that lysosomes are also inside-negative<sup>12,13</sup>, and the receptor's binding sites are on the cytosolic, electrically positive surface.

There is considerable precedent for potential-dependent behaviour of peptides and proteins in membranes. Electrical conductance can be modulated asymmetrically by antibiotic ionophores<sup>14</sup>, toxins<sup>15,16</sup>, transport molecules isolated from

biological systems<sup>17,18</sup>, immune cytotoxic factors<sup>19,20</sup>, and by 'gating' components of the sodium and potassium channels of nerve<sup>21,22</sup>. However, none of the physiologically interesting examples of these processes is understood in much detail. Wickner and co-workers<sup>23</sup> have speculated that an electrical gradient might drive newly synthesized M13 coliphage coat

proteins across the host membrane. This work on HBP provides the first direct evidence for the voltage-dependent translocation of a membrane protein across a membrane.

We thank K. Bridges and H. Tsunoo for purified HBP and ASOR, and G. Ashwell for stimulating discussions and encouragement.

# The C1q receptor site on immunoglobulin G

D. R. Burton, J. Boyd, A. D. Brampton, S. B. Easterbrook-Smith, E. J. Emanuel, J. Novotny, T. W. Rademacher, M. R. van Schravendijk, M. J. E. Sternberg & R. A. Dwek

Department of Biochemistry and Laboratory of Molecular Biophysics, South Parks Road, Oxford OX1 3QU, UK

*We propose that the binding site for the complement subcomponent C1q on immunoglobulin G involves the last two (C-terminal)  $\beta$ -strands of the C<sub>2</sub> domain. This region contains a large number of accessible and highly conserved charged residues and charge is postulated as an important component of the C1q-IgG interaction. The conclusions are reached on the basis of accessibility and sequence conservation analyses of C<sub>2</sub> amino acid residues, the use of specific inhibitors and chemical modification studies.*

ANTIBODIES are the basis of the body's defence against infection. This central role is expressed in the functional versatility of the antibody molecule and realized through its unique structure. Thus, the organization of the antibody molecule into domains (Fig. 1a) allows recognition of a virtually unlimited range of antigens by the variable part of the structure, while the constant part mediates a small number of effector systems related to antigen elimination and/or immobilization. The best characterized of these effector systems is the classical pathway of complement.

Complement is a cascade process<sup>1</sup> generating a repertoire of biological activities with consequences<sup>2</sup> that are both local (for example, cytolysis and increased vascular permeability) and systemic (such as induced peripheral leukocytosis). Although the complement system presumably evolved as a beneficial antimicrobial mechanism, its inappropriate activation may lead to a variety of harmful consequences such as tissue damage secondary to complement-induced leucoembolization<sup>3</sup>, as occurs in adult respiratory distress syndrome, or complement-mediated cytolysis *in situ* such as occurs in autoimmune disorders<sup>2</sup>.

The triggering event in the classical pathway is the binding of the first component C1 to the Fc region of aggregated immunoglobulin. C1 is a macromolecular complex of three subcomponents—C1q, C1r and C1s—of total molecular weight (MW) approximately 700,000. The binding site for the Fc region of Ig is found on the C1q subcomponent (MW ~400,000). The structure of C1q has been proposed by Reid and Porter<sup>4</sup> as having the appearance of a 'bunch of tulips' (Fig. 1b). Eighteen chains, each some 200 amino acid residues long, are linked in threes in the base and stalk regions to form collagen-like triple helices. Each of the six fibres terminates in a globular head region which is thought to contain the Fc binding site(s).

The crystallographic structure of human Fc from pooled IgG

has been determined to 3.5 Å by Huber and colleagues<sup>5</sup>. The overall structure has been described as a 'Mickey Mouse', with the C<sub>2</sub> domains forming the ears and the C<sub>3</sub> domains the head (Fig. 1c). The tertiary structure of both these domains corresponds to the 'immunoglobulin fold'. However, whereas the pair of C<sub>3</sub> domains are in close interaction (Fab 'C-like' pairing<sup>6</sup>), the C<sub>2</sub> domains show no interaction with one another. The carbohydrate chains attached to Asn 297 are in between the C<sub>2</sub> domains. Although it is generally accepted that recognition of IgG by C1q occurs via a site on the C<sub>2</sub> domains<sup>6,7</sup>, the precise location of the amino acid residues constituting this site has not been described.

We now propose an identification of the C1q binding site based on a novel approach containing three lines of investigation. These are: (1) amino acid residue accessibility and sequence conservation analyses which are used to locate potential binding regions on Fc; (2) specific inhibitors of the protein-protein interaction (IgG-C1q) which are investigated to give information on the nature of the groups involved in the interaction; (3) specific chemical modifications of residues on Fc and C1q which are studied to implicate particular types of residues in the protein-protein interaction.

The C1q binding site we propose is rather novel in that it consists mainly of charged side chains (glutamate and lysine) on the last two (C-terminal end)  $\beta$ -strands of the C<sub>2</sub> domain. The approach used may prove to be generally useful in studying protein-protein interactions, in particular, where a detailed structure is known for one of the proteins but little structural information is available for the second protein or the complex formed between the two.

The residues in the C<sub>2</sub> domain involved in interaction with C1q should fulfil two criteria. First, they should be accessible for C1q binding, that is, not buried in the interior of the domain. This can be quantified by the surface area of the residue which

**Fig. 1** *a*, The domain structure of IgG. The different domains are shown by circled regions where V signifies variable domain, C constant domain,  $\gamma$  the heavy chain and L the light chain. Various proteolytic fragments Fc, pFc, Fab and Fv are also indicated. The IgG molecules of different classes and species differ most noticeably at the hinge region. Human IgG1 is represented here. *b*, Molecular structure of C1q proposed by Reid and Porter<sup>4</sup> (after whom the figure is taken) to account for the effects of collagenase and pepsin digestion and the dimensions and shape of the images seen in the electron microscope. Analysis and sequencing of the three types of polypeptide chain present show clear similarities between them, notably the repeating collagen-like triplets of residues which occupy some 85 positions starting near the N-terminal end. The characteristic Gly-X-Y pattern, where the residue Y is often either hydroxyproline or hydroxylysine, is broken at position 39 of the A chain and 36 of the C chain, allowing the bend of the triple helices forming each stalk away from those in the base region. *c*, The structure of the Fc fragment from pooled human IgG after Huber *et al.*<sup>5</sup>. ●,  $\alpha$ -C carbon positions; ○, approximate centres of carbohydrate hexose units. The very approximate locations of the main hydrophobic patches of the molecule (see Table 1 and text) are represented as shaded areas. *d*, Peptide chain folding of a constant domain<sup>6</sup>. The segments fx1-4 (unshaded) and fy1-3 form two roughly parallel faces of anti-parallel  $\beta$ -pleated sheet linked by an intra-chain disulphide bridge (filled rectangle, Cys 261 to Cys 321 in C $\gamma$ 2). Between the  $\beta$ -pleated segments are other segments (b1-6) forming helices, bends and other structures. Segments fx3, fx4, fy1 and b4 are foreshortened in this three-dimensional representation. A generalized view of constant domain folding is represented here—the C $\gamma$ 2 domain shows some deviations from this description, chiefly in b3 and fx3 (ref. 5).

can be in contact with the solvent. Second, they should be highly conserved in IgG molecules that bind C1q. This follows from the observation of the cross-species reactivity of C1q and IgG<sup>8,9</sup>. These two criteria are now considered separately.

### Accessibility analysis

In exploring those residues accessible for C1q binding, an analysis would ideally be carried out on the C $\gamma$ 2 domain of IgG in an immune complex. However, the only structure available at sufficient resolution is that of the isolated Fc fragment determined by crystallography to 3.5 Å (ref. 5). In using this structure in the accessibility analysis, the assumption is thus made that Fc has essentially the same structure in the isolated fragment and in intact IgG. Further, it is assumed that antigen binding does not significantly perturb the Fc structure in IgG, in line with evidence from this and other laboratories<sup>10</sup>.

Starting with the crystallographic structure of the Fc fragment for which the positions of most of the atoms are known, those residues of the C $\gamma$ 2 domain in contact with solvent can be identified using a computer program<sup>11</sup>. This program calculates the solvent contact area by constructing the van der Waals surface of the protein and 'rolling' a sphere (in our case of 1.4 Å radius to represent a water molecule) over the surface. It is found that of the 104 residues of the C $\gamma$ 2 domain, about 72 are accessible to water (contact area  $>5 \text{ Å}^2$ ).

As the energy which drives protein-protein interactions often comes from shielding protein hydrophobic surfaces<sup>12</sup> (the area

buried being proportional to the free energy of the interaction,  $1 \text{ Å}^2 \text{ contact area} \approx 80 \text{ cal mol}^{-1}$ )<sup>13</sup>, first interest centres on accessible residues which are predominantly nonpolar. Groupings of residues to form exposed hydrophobic patches are of particular interest and the principal features of those located in the C $\gamma$ 2 domain are summarized in Table 1 (see also Fig. 1c, d).

Table 1 shows that 35 residues have their nonpolar atoms (main chain  $\alpha$ -C, side chain C excepting those attached to O or N and side chain S) accessible to solvent with a contact area  $>5 \text{ Å}^2$ . Of these, 27 are clustered into four large patches ( $>100 \text{ Å}^2$ ) (shown in Fig. 1) and the remaining residues are found in two smaller patches and as isolated residues.

The location of patches 1-3 makes it unlikely that they are involved in C1q binding (Table 1, Comments). Use of our second criterion that a potential C1q binding site should be conserved between species then helps to eliminate the remaining patches (Table 1, Conservation).

In the absence of suitable accessible hydrophobic residues the next stage is to examine hydrophilic residues. Most of these are, of course, solvent accessible and prime interest now centres on the conservation between species of these hydrophilic residues.

### Sequence comparison analysis

Nine C $\gamma$ 2 primary structures are available<sup>14-16</sup>: three human myeloma proteins [ $\gamma$ 1 (Eu),  $\gamma$ 3 (Zuc),  $\gamma$ 4 (Vin)], rabbit chain, guinea pig  $\gamma$ 1 and  $\gamma$ 2 chains, two mouse myeloma proteins [ $\gamma$ 1 (MOPC 21),  $\gamma$ 2a (MOPC 173)] and mouse  $\gamma$ 2b chain. Human

**Table 1** The exposed hydrophobic patches of the C<sub>γ</sub>2 domain of Fc from human IgG1

| Patch  | Approximate area (Å <sup>2</sup> ) | Residues  | Conservation   | Comments  |
|--|------------------------------------|---|--|---|
| Concave surface of the 4-strand β-sheet layer (x face) | 150                                | Phe 241, Phe 243, Pro 244<br>Lys-Pro-Lys 246-248<br>Val-Val-Val 262-264 | Very highly conserved. All residues, except Pro 247, identical in nine C <sub>γ</sub> 2 primary structures | Mostly covered by Fc carbohydrate*. Lys-Pro-Lys is very close to C <sub>γ</sub> 3 and probably inaccessible to C1q  |
| N-proximal bend (b6)                                   | 130                                | Lys-Ala-Leu-Pro-Ala-Pro-Ile 326-332                                     | Not highly conserved. Only Pro 329 and Ile 332 identical in nine C <sub>γ</sub> 2 primary structures       | Hinge nearby could increase hydrophobic area. In the case of antibody recognition of cell-surface determinants, C1q binding to this patch would be under severe, if not prohibitive, steric restrictions from the cell  |
| C-proximal bulge (b1, b5)                              | 100                                | Met-Ile 252-253<br>Val-Leu 308-309                                      | Not highly conserved. Only Ile 253 identical in all nine C <sub>γ</sub> 2 sequences                        | C1q binding to this patch would necessarily involve contact with C <sub>γ</sub> 3 residues (compare with protein A <sup>22</sup> ). The ability of the Fabc fragment (IgG with the C <sub>γ</sub> 3 domains removed) to bind C1 and activate complement by the classical pathway <sup>7</sup> argues against the involvement of this patch in C1q binding |
| Outside edge between β-sheet layers (fx3, fx4)         | 100                                | Val 279<br>Ala-Lys 287-288<br>Lys-Pro 290-291<br>Val 303<br>Leu 306     | Not highly conserved. Only Ala 287 and Leu 306 identical in nine C <sub>γ</sub> 2 primary structures       |   |
| C <sub>γ</sub> 2/C <sub>γ</sub> 3 switch region        | 40                                 | Ala-Lys 339-340   | Ala 339 found in only four of nine C <sub>γ</sub> 2 sequences  | Relatively small area   |
| b3 bend  | 40                                 | Val 282, Val 284  | Val 282 (most of nonpolar area) is identical in six of nine C <sub>γ</sub> 2 sequences                     | Relatively small area   |
| Isolated residues                                      | Total area 60 Å <sup>2</sup>       | Pro 271, Lys 274, Tyr 296, Ile 336                                      | Ile 336 highly conserved, others not   |   |

\* The crystallographic coordinates used in this analysis did not include those for the carbohydrate.

IgG1, IgG2 and IgG3, and rabbit and mouse IgG2a and IgG2b proteins are known to activate complement. Two mouse IgG1 subclasses—one activating complement, one not—have recently been proposed<sup>17</sup>. The C1q binding properties of MOPC 21 are not known. Guinea pig IgG1<sup>16</sup> and human IgG4 proteins are known not to bind C1, although the Fc fragment of IgG4 does<sup>18</sup>. This latter observation has led to the suggestion that the C1q binding site may be present in the primary structures of all IgGs but unavailable in some cases because of, for example, obstruction by the Fab arms<sup>18</sup>. Furthermore, comparison of the C<sub>γ</sub>2 sequences reveals no obvious correlation between primary structure and complement-fixing ability. Hence, all nine C<sub>γ</sub>2 primary structures are considered in the detailed sequence comparison here.

The analysis reveals that of the 104 positions in the nine C<sub>γ</sub>2 domains, 39 are identical throughout, and a further 36 may be considered conservative replacements (defined as any having a chemical relatedness index >0 according to McLachlan<sup>19</sup>; in the case of uncertainties, homology was maximized). Nineteen positions are particularly variable in that they show more than

one non-conservative substitution. As expected, these are almost exclusively surface residues and include two distinct regions: Gly-Val-Gln 281-283 and His 285 on bend b3 and Lys 288, Lys-Pro-Arg-Glu 290-294 on the fx3 sheet (nomenclature according to Fig. 1c). Interestingly, this latter region has been proposed as a C1q binding site by Brunhouse and Cebra<sup>16</sup>.

If we now consider the 39 invariant residue positions, some can be readily eliminated from being involved in C1q binding: 10 are buried, 5 are covered by carbohydrate and 2 (Asn 297, Thr 299) are related to sugar attachment. It then becomes necessary to establish positions for which invariance can be understood on structural grounds without invoking functional significance.

A comparison of the alignments of the primary structures of 23 constant domains<sup>20</sup> (including λ, κ, C<sub>H</sub>1, C<sub>H</sub>2, C<sub>H</sub>3 and the 'extra' domains of various species) is now used to reveal whether any of the remaining 22 invariant positions are involved in general immunoglobulin domain architecture. The percentage of domains having the same amino acid residue as C<sub>γ</sub>2 at the same position (the identity index) is computed. A high index

**Fig. 2** A stereoview of the region of the C<sub>γ</sub>2 domain containing the proposed C1q binding site. Residues 316 and 317 are part of a bend structure; residues 318-322 form a β-strand (fy2); residues 323-331 are on a bend as shown; residues 332-337 form a β-strand (fy3) antiparallel to fy2 and residues 338-340 continue into the C<sub>γ</sub>3 domains.

indicates that the residue is important for the constant domain fold in general, a low index indicates it is unusual for constant domains and possibly associated with the unique function of the C<sub>γ</sub>2. Table 2 shows identity indices for the 22 key invariant positions; Leu 306 and Trp 313 seem to be general features of constant domains.

At this stage, however, the most striking observation is the emergence of the contiguous residues on the  $\gamma$  face, Gly-Lys-Glu 316–318, Lys 320 (b5, fy2), Thr 335, Ser 337 and Lys 338 (fy3) (underlined, Table 2), as a potential binding region (Fig. 2). The charged residues have noticeably low identity indices. Further examination of other exposed residues in this region reveals that Lys 322 (fy2) is conserved as Lys in eight of nine C<sub>γ</sub>2 domains, being replaced by Arg in guinea pig IgG2 and having an identity index of 13%. Pro 331 (b6) (replaced by Thr in guinea pig IgG1), Glu 333 (fy3) (Thr in guinea pig IgG1) and Lys 340 (e2) (Arg in rabbit), with identity indices of 35, 26 and 9%, are similarly conserved. The entire region (Fig. 2) is then one of exposed, highly conserved, mostly charged (five Lys, two Glu) residues.

Of the remaining residues of Table 2, Thr 260 and Arg 301 could be involved in interaction with the carbohydrate; Ser 239, Asp 265 and Ser 267 may be involved in hinge or Fab arm conformation; Lys 248 (possibly interacting with Glu 380) and His 310 are at the C<sub>γ</sub>2/C<sub>γ</sub>3 interface; Pro 329 is involved in bend architecture and Gly 341 in the C<sub>γ</sub>2/C<sub>γ</sub>3 switch region. Reasons for conservation of the remaining residues, Ala 287, Ile 253, Ile 332 and Ile 336, are unclear.

Note, finally, that the carbohydrate forms an exposed, probably conserved, continuous region and therefore must also be considered as a potential or part of a potential C1q binding site.

## Inhibitor studies

In the light of the charged potential binding region on Fc discussed above, we have compared the ability of several salts, in a variety of experimental conditions, to inhibit C1q binding to anti-ovalbumin-ovalbumin aggregates. Table 3 compares the  $K_{50}$  values for a number of inhibitors.

Figure 3a illustrates the well known dependence of C1q binding to antibody aggregates on NaCl concentration<sup>21,22</sup> and further reveals a marked anion dependence of inhibitory ability,  $I^- > Cl^- > F^-$ . Appropriate controls show that salt is not dissociating the aggregates over the concentration range used<sup>23</sup>. Figure 3 also shows that the C1q-antibody aggregate reaction is reversible and therefore, at a given NaCl concentration, can be

**Table 3** Comparison of the ability of a number of molecules to inhibit the C1q-antibody aggregate reaction

$K_{50}$  indicates the concentration of inhibitor at which C1q binding to antibody aggregates assayed as described in Fig. 3 legend is reduced by 50% from the maximum value (compare with Fig. 3a). For the inorganic ions, NaCl was present in concentrations such as to maintain a constant ionic strength of 170 mM. For the polyions and carbohydrates, the NaCl concentration was constant at 170 mM. > Indicates a full inhibition curve was not obtained and the value quoted is an extrapolation. >> Indicates that no inhibitory effect was observed up to the quoted concentration. For polylysine an upper limit is described because of uncertainties in the molecular weight of this polymer.

\* NaCl = 120 mM.

described as an equilibrium process:

where AbAg represents antibody aggregate, measured in units of antibody concentration, and C1q · AbAg the complex, measured as the amount of C1q bound to the aggregates. Binding studies at variable C1q and NaCl concentration (Fig. 3b) can then be used to estimate a phenomenological dissociation constant,  $K_{obs}$ , at each NaCl concentration for this equilibrium. The plot of  $\log K_{obs}$  against  $a_{\pm}$  ( $a_{\pm}$  defined as  $a_{NaCl}^{1/2}$ ) in Fig. 3c reveals that  $K_{obs}$  increases with increasing NaCl concentration. This increase, together with a fall in C1q binding capacity, is responsible for the inhibitory effect of NaCl seen in Fig. 3a. The gradient of a  $\log K_{obs}$  against  $\log a_{\pm}$  plot can be interpreted in terms of a general equation for the effect of an electrolyte on a macroion equilibrium<sup>24</sup>. Although a detailed analysis is probably not justified by the limited scope of our data, the clearly positive gradient of the  $\log K_{obs}$ - $\log a_{\pm}$  plot indicates that ions participate directly in the association of C1q and antibody aggregate. The most straightforward interpretation of the slope is that a net total of  $12 \pm 2$  ions are released when 1 molecule of C1q binds to antibody aggregates. A similar plot for CaCl<sub>2</sub> between 22 and 50 mM gives a slope of  $15 \pm 2$ . Although both cations and anions could be involved, some indication of the importance of anions is provided by the dependence of inhibitory ability on the lyotropic series (Fig. 3a, Table 3),  $SCN^- > I^- > Cl^- > F^- > SO_4^{2-}$  and the relative potency of organic

Underlined residues are those on the  $\gamma$  face, forming a potential binding region (see text).

anions such as dinitrophenyl (DNP) ethyl phosphate and ATP as inhibitors (Table 3). It is interesting that the  $K_{50}$  values observed for NaCl (~250 mM) and ATP (~10 mM) are comparable with the binding constants to the organic phosphate site of oxyhaemoglobin of ~50 mM (NaCl) and ~2.5 mM (ATP), respectively<sup>24</sup>. The inhibitory ability of organic ions listed in Table 3 may explain the widespread observation of various polypeptides (all containing negative charges) as inhibitors of the C1q-IgG interaction<sup>25,26</sup>.

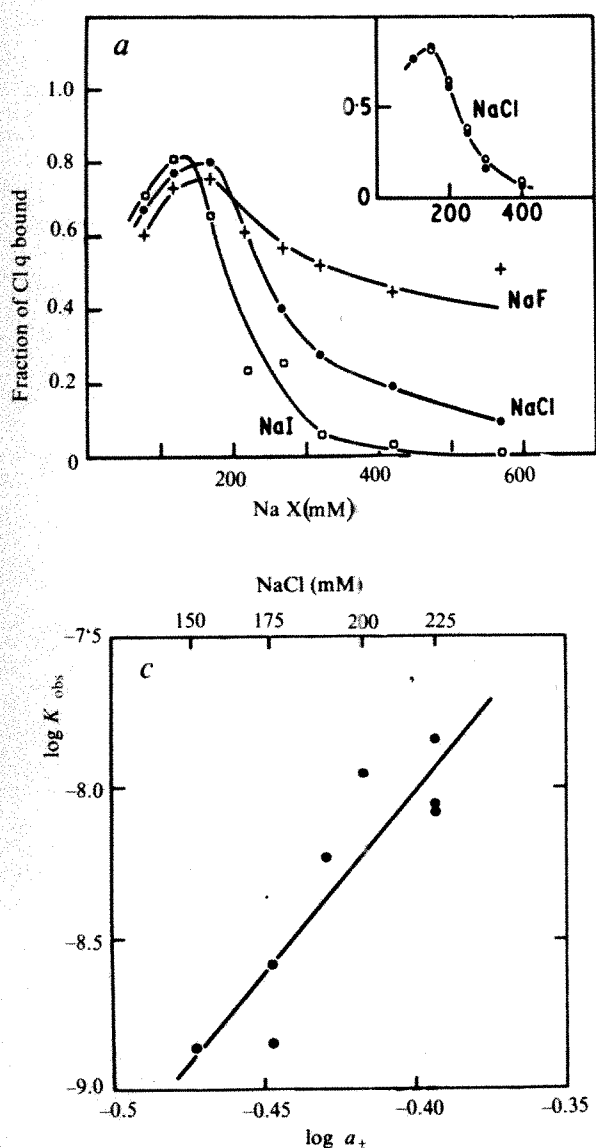

That the interaction between C1q and antibody-antigen aggregates involves ions does not, of itself, rule out the possibility that other interactions are important. In particular, the Fc carbohydrate could be involved because it fulfils the criteria of accessibility and conservation. However, neither monosaccharides (Table 3) nor the carbohydrate isolated from transferrin (similar to the human Fc carbohydrate) had any significant inhibitory ability<sup>27</sup>. The inhibition by heparin is probably due to its polyionic nature.

### Chemical modification studies

The effect of chemical modification of a number of groups on both C1q and rabbit IgG on the interaction between the two has been studied. Table 4 shows that modification of  $19 \pm 1$  (30%) of the lysines on IgG by methyl acetimidate, a mild reagent leaving the positive charge on lysine intact, produces no decrease in the binding capacity of IgG aggregates for C1q, with a significant increase in the dissociation constant. A qualitatively similar

result is obtained for the modification of 4 or 10 lysines using acetic anhydride. A decrease in binding capacity and an increase in  $K_d$  are observed for modification of  $12 \pm 2$  carboxyl groups on IgG by glycine methyl (or ethyl) ester (Table 4). (A recent report describes a similar observation of the effect of carboxyl modification on the C1q-human Fc interaction<sup>28</sup>.) Control experiments in these and other modification experiments involved showing that: (1) circular dichroism (CD) spectra and (2) precipitin curves of modified and unmodified IgG were the same. A further control for methyl acetimidate modification of lysines and cyclohexanedione modification of arginines (see below) was that similar effects were observed whether the modification was carried out before or after antigen aggregation.

In contrast to the above, cyclohexanedione modification of  $10 \pm 1$  arginines in IgG, of which 7 or 8 were estimated to be in the C<sub>γ</sub>2 domains, has little effect on C1q binding, as shown in Table 4. The number of residues modified in the C<sub>γ</sub>2 domains was determined from pepsin digestion of modified IgG as the difference between the number modified in intact IgG and the number modified in the F(ab')<sub>2</sub> and pFc' fragments<sup>29</sup>. Six of the seven C<sub>γ</sub>2 arginine residues in rabbit IgG are found in the general region between x and y faces. As the modification described involves complexing a very bulky cyclohexanedione-borate group to each arginine, our results provide evidence against the involvement of this region in C1q binding, which includes the region proposed by Brunhouse and Cebra as a C1q binding site<sup>16</sup>. This conclusion is also substantiated by the absence in rabbit from this region of the C<sub>γ</sub>2 domain of lysine

**Fig. 3** The involvement of ions in the C1q-antibody aggregate reaction. *a*, The binding of C1q to antibody aggregates as a function of sodium halide concentration. Human C1q (ref. 38) and <sup>125</sup>I-labelled human C1q (ref. 39) were prepared as described elsewhere. Rabbit antisera were prepared by the injection of ovalbumin, emulsified in Freund's complete adjuvant 1:1, into each hind footpad and shoulder muscle. The anamnestic response was elicited by intraperitoneal injection of alum-precipitated ovalbumin. Purification to yield IgG was according to ref. 40. The C1q binding assay involved incubating <sup>125</sup>I-labelled C1q (typically 1–30 μg ml<sup>-1</sup>) with antibody aggregates (typically 25 μg ml<sup>-1</sup>) in a 12 mM Tris, 0.15% gelatin, pH 7.2, solution of the appropriate salt concentration at 37 °C for 45 min. Bound and free <sup>125</sup>I-labelled C1q were determined after centrifugation. The inset data points were obtained as normal (●) or (○) by incubating as above for 30 min at 400 mM NaCl, performing the appropriate dilution to the specified NaCl concentration, reincubating and assaying in the normal manner. *b*, Representative binding curves for the reaction of C1q and antibody aggregates at varying NaCl concentration. Binding was measured as in *a*. The curves were fitted to a hyperbola using a nonlinear least squares program. The program yielded a value for  $K_{obs}$ , the phenomenological dissociation constant for the reaction, at each NaCl concentration. It was found that 10–20% (depending on the C1q preparation) of the C1q was not available for binding to antibody aggregates (possibly through denaturation). The binding curves shown have been appropriately corrected. *c*, log  $K_{obs}$  as a function of the log of the ion activity parameter,  $a_{\pm}$ , for the C1q-antibody aggregate reaction in the presence of NaCl.  $a_{\pm}$  is defined as the square root of the NaCl activity ( $a_{NaCl}^{1/2}$ ). The plot makes use of the type of data seen in *b*. The slope of the plot is  $12 \pm 2$ .

**Table 4** The effect of various chemical modifications of groups on IgG and C1q on the interaction between C1q and antibody aggregates

| Modification                          | Extent of modification (per IgG or C1q molecule) | $K_d$ modified<br>$K_d$ unmodified | Capacity modified<br>Capacity unmodified |

| Cyclohexanedione                      | 18 ± 1 (10%)                                     | —                                  | 0  |

For each modification a C1q binding curve is obtained (compare with Fig. 3b) and compared with unmodified reactants. The  $K_d$  and capacity of IgG for C1q in each case were determined from the binding curves as described in Fig. 3b legend. Methyl acetimidate modification<sup>33</sup> of lysines on IgG (10 mg ml<sup>-1</sup>) was carried out at pH 8.06 and 4 or 25 °C in 0.1 M triethanolamine using 0.1 M methyl acetimidate for 3 min (30% modification) or 10 min (60%). The reaction was stopped by lowering the pH to below 8.0. Similar conditions were used for modification of C1q with 7 min modification time and the inclusion of 150 mM NaCl in all buffers. Acetic anhydride modification<sup>34</sup> of lysines was carried out at pH 5.1, 0 °C in 1 M sodium acetate using 0.5% (v/v) acetic anhydride for 5 min. The reaction was stopped by adding a large excess of lysine. The extent of lysine modification for both modifying reagents was determined using trinitrobenzene sulphonate as described elsewhere<sup>35</sup>. Arginine modification<sup>29,36</sup> was carried out using 1 M cyclohexanedione in 0.2 M sodium borate at pH 9 and 25 °C for 1 h. The reaction was stopped by lowering the pH to 4 and the extent of modification estimated from amino acid analysis. Similar conditions were used for modification of C1q with 45 min modification, a lowering of the pH to 6 to stop the reaction and the inclusion of 150 mM NaCl in all buffers. Carboxylate modification<sup>35</sup> of IgG made use of a 30–50-fold (over IgG) molar excess of carbodiimide in 1 M glycine methyl (or ethyl) ester at pH 4.75 and 25 °C for appropriate times. Excess sodium acetate was added to stop the reaction and the extent of modification estimated from amino acid analysis. Tryptophan modification<sup>37</sup> of IgG was carried out using a 300-fold (over IgG) excess of hydroxynitrobenzyl bromide in 0.1 M sodium acetate at pH 4.5. The extent of modification was estimated spectrophotometrically. Modifications were carried out on IgG in the range 10–70 µM.

residues which are shown here to be important in the interaction with C1q.

In sharp contrast to IgG, cyclohexanedione modification of 18 arginines on C1q (equivalent to 3 residues modified per C1q monomer unit) abolishes binding to IgG aggregates whereas methyl acetimidate modification of 75 ± 15% of the lysines on C1q has little or no effect.

## Conclusions

The accessibility and conservation analyses described strongly suggest that a charged region on the last two (C-terminal end)  $\beta$ -strands of the C<sub>2</sub> domain of IgG has functional importance. Specific inhibitor and chemical modification studies are consistent with this function being the binding of the complement subcomponent, C1q, and we therefore propose that this charged region (Fig. 2) contains residues which are directly involved in the C1q binding site on IgG.

At the other end of the antibody molecule, recognition of antigen generally involves binding of the antigen in a cleft or groove in the antibody structure. On the basis of our hypothesis, recognition of C1q would involve quite different principles. Thus, the Fc site proposed by us consists of a virtually planar array of (mostly charged) residues which is unlikely to act as or bind into a cleft or groove. It is far more probable that recognition involves some form of surface 'matching' of charged

residues on Fc and C1q. This kind of protein-protein interaction involving charge has been described in the extended salt-bridge system between subunits in tobacco mosaic virus (TMV)<sup>30</sup>. Whereas TMV uses residues on helices, our Fc site consists mainly of residues on two  $\beta$ -strands. A surface complementary to this would be provided by suitably arranged charged residues on two  $\beta$ -strands of C1q.

The type of approach we have adopted here is limited by the fact that it is not possible to describe the size of the proposed C1q binding site precisely. However, examination of Fig. 2 shows that Glu 318, Lys 320, Lys 322, Pro 331, Glu 333, Thr 335 and Ser 337 are fairly close in space and Gly 316, Lys 317, Lys 338 and Lys 340 (the residues not in the  $\beta$ -strands) are more distant. The former residues form a roughly planar area of approximately 150 Å<sup>2</sup>. The location of this area in the C<sub>2</sub> domain is such that a bulky molecule such as a C1q head could be denied access for certain orientations of the Fab arms. In addition, our data do not definitively rule out the possible involvement of the contiguous carbohydrate moieties (compare with ref. 31).

Clearly, a crystallographic structure of Fc and C1q heads would provide a definitive identification of the C1q binding site. Progress in this formidable task could be made with the availability of a crystal structure for C1q heads. For instance, matching of this structure with that of Fc could be considered. In the short term, however, exhaustive testing of chemical modifications of Fc may allow selective labelling of particular residues in the site which can be identified by the usual protein chemical methods. Alternatively, crystallographic studies of Fc in the presence of an inhibitor could be useful. Such chemical modification and crystallographic studies are now in progress.

Finally, it is interesting that preliminary results on IgM (in collaboration with A. Feinstein) again indicate the importance of charged groups in the recognition of C1q. It remains to be shown whether the same site on C1q is recognized for both IgG and IgM.

We thank Professors R. R. Porter and D. C. Phillips for their continued interest and encouragement, Professor R. J. P. Williams, Drs K. Reid, A. Feinstein, F. E. Cohen and I. O. Walker for useful discussion, Professor R. Huber for supplying the coordinates of the Fc crystal structure and Dr S. R. Martin for CD measurements. This work was supported by the MRC and is a contribution from the Oxford Enzyme Group. D.R.B. is an MRC Training Fellow, S.B.E. is a Junior Beit Fellow, E.J.E. is an F. J. Moore Fellow, T.W.R. is a Fellow of the Institute for Medicine and Mathematics and M.J.E.S. is a Stothert Fellow of the Royal Society. J.N. held a Royal Society Fellowship during this study.

## LETTERS

### Prominent VLBI cores in powerful radio sources with arc second structure

Gopal-Krishna\* & E. Preuss

Max-Planck-Institut für Radioastronomie, Bonn, FRG

R. T. Schilizzi

Netherlands Foundation for Radio Astronomy, Dwingeloo, The Netherlands

VLBI and aperture-synthesis techniques have produced better understanding of the structural details of extragalactic radio sources of both compact ( $<1$  arcs) and extended ( $>10$  arcs) types. Much less is known about the radio morphologies of sources with an overall size of just a few arc seconds, though such information is essential for understanding the evolutionary link between compact and extended sources. It has been predicted that the radio nucleus of a double source should appear Doppler brightened due to relativistic beaming, if the source axis is oriented close to the line of sight<sup>1–3</sup>. To investigate this, we examined two samples of double radio sources whose axes are expected to be inclined respectively at large and small angles from the line of sight. The statistics of the 'core fraction'—fraction of the total flux of the source which is contributed by its nuclear core at some reasonably high frequency, say 5 GHz, can then be obtained. Sources with large inclination angles would probably dominate the samples of extended, well-resolved double sources and hence their core-fraction can be readily estimated from published aperture synthesis surveys. Double sources oriented close to the line of sight are expected to be more common in samples containing only those sources whose angular sizes are a couple of times smaller than the median size for that flux density range. A large, unbiased sample of this type can be constructed using the nine Ooty lunar occultation lists (see ref. 4). We have selected all sources lying north of declination  $-25^\circ$  for which a flux density  $\geq 1$  Jy and an overall size between 1 and 4 arc s have been estimated at 327 MHz in the occultation observations. These 30 'few-arc second' sources are expected<sup>5</sup> to be distant objects ( $z > 0.3$ ) and hence intrinsically powerful radio emitters radiating  $>10^{33}$  erg s<sup>-1</sup> Hz<sup>-1</sup> at 327 MHz ( $H_0 = 50$  Km s<sup>-1</sup> Mpc<sup>-1</sup>,  $q_0 = 0.5$ ). Sources of such high radio power have a classical double morphology<sup>6</sup> and there exists evidence for double structure in 8 of these 30 few-arc second sources. We report here a search for compact cores among these sources by VLBI at 5 GHz using the large antennas at Effelsberg and Westerbork which provide a minimum fringe spacing of 0.045 arc s at this frequency. Radio cores were found to be much more prominent in this representative sample of 30 few arc-second sources, as compared with the cores found typically in extended double sources.

The nine Ooty occultation lists provide high resolution data for an unbiased sample of 711 radio sources in the Moon's path, down to a flux level of  $S_{327} \sim 0.25$  Jy. Due to the low frequency of this survey (327 MHz), it is believed that the sources have been selected without bias in orientation. Parts of these data have been used to study the angular size properties of weak

extragalactic radio sources<sup>5,7,8</sup>. By excluding all sources with  $S_{327} < 1$  Jy or  $\delta < -25^\circ$ , we first formed a sample A of 266 occultation sources, which should have properties very similar to the 4C complete sample (defined by  $S_{178} > 2$  Jy). The median angular size<sup>9</sup> of sources in sample A is  $\sim 12$  arc s and three-quarters of them have been resolved in the occultation observations at 327 MHz (these low-frequency observations are suitable for measuring the overall size because the outer radio structure usually has a steep spectrum). The optical identification work for sample A has been carried out using PSS plates and using mostly a combined 'radio+optical' position accuracy of better than a few arc seconds, aided by the knowledge of radio structure. It was found that  $\sim 39\%$  of the sources have optical counterparts brighter than the PSS plate limit<sup>4</sup>.

Our sample of 30 few-arc second sources was formed by selecting from the sample A all those sources for which occultation scans along position angles at least  $20^\circ$  apart had been observed and the derived maximum angular size at 327 MHz fell in the range 1–4 arc s. Note that a comparable number of similarly extended sources may have failed to be selected because, either the coverage in position angle during occultations was not wide enough or the angular resolution attained was insufficient to resolve them (the achieved resolution for the same source can vary by up to a factor of  $\sim 2$  depending on the observational circumstances such as the speed of the Moon's limb relative to the source<sup>9</sup>).

The VLBI observations of the 30 few arc-second sources were made on 11 and 12 January 1980 for 26 h, using the 100-m Effelsberg telescope and 11 of the 14 telescopes of the Westerbork array in total power mode. The latter provides at the zenith a beamwidth of 7 arc s (EW)  $\times$  10 arc min (NS) and is equivalent to an 83-m dish in collecting area. A central frequency of 4,996 MHz and right circular polarization were used.

For each source, up to three short observations each lasting 10–15 min were made, interspersed with calibration observations. The minimum fringe spacing was 0.045 arc s, increasing by up to a factor of 3 for the southern sources. We also measured, on the first day, the integrated flux densities of all these sources at Effelsberg by taking cross scans at the source positions (known to an accuracy of  $\sim 1$  arc s).

The VLBI data recording was done using the standard MKIIc system with a bandwidth of 2 MHz. A hydrogen maser oscillator at Effelsberg and a rubidium oscillator at Westerbork provided the time and frequency standards. The cross correlation and further reduction of the data were carried out at the Max-Planck-Institut für Radioastronomie, Bonn.

The values of integrated flux densities  $S_T$ , calibrated on 3C161 and 3C286, are given on the scale of Baars *et al.*<sup>10</sup>. These have an r.m.s. uncertainty of  $\Delta S_T(\text{mJy}) = [(5)^2 + (0.05 S_T)^2]^{1/2}$ . The correlated flux density scale was calibrated using the sources 0J287, 2134+004 and 3C454.3 whose flux densities measured at Effelsberg during the observations were 2.7, 9.8 and 8.3 Jy at 5 GHz, respectively. The calibration factor for all three sources has an r.m.s. scatter of 7%. Using the observations of these strong calibration sources and of a few weaker sources belonging to our observed sample (Table 1), the loss of correlated amplitude due to phase drifts in oscillators was determined as a function of the coherent integration time. Accordingly, a correction of 20% to the correlated amplitude was applied for a

‡ D, double; S, single; PD, possible double; EXT, bright core with a faint extension of a few arc s.

typical observation of 9 min. The r.m.s. noise for a coherent integration over such a period is  $\sim 8$  mJy. The formal error of the correlated amplitude  $S_c$  is the quadratic sum of this noise and  $0.05S_c$ .

The results for the 30 few-arc second sources are summarized in Table 1, together with their parameters at 327 MHz, derived from the occultation observations, and their optical identifications. The VLBI results include the fringe spacing FS, position angle PA of the projected baseline and the correlated flux density  $S_c$  at 5 GHz for each observation. The 'core fraction' at 5 GHz ( $C_5$ ) gives the ratio of the mean correlated flux density of a source to its integrated flux density. The last column gives the fringe detection class: *a* indicates all detections above 5 r.m.s. (12 sources) and *b* the detections between 3.5 and 5 r.m.s. in at least one observation (9 sources). We consider the above 21 sources to be clearly detected because in each case, the maximum correlated amplitude: (1) lies well above the noise and

in the correct frequency side band; (2) it lies within the same range of three delay channels in which the calibration sources were also detected; and (3) its residual fringe rate falls in a narrow range from  $-58$  to  $-74$  mHz which is similar to the value  $-68 \pm 4$  mHz observed for the calibration sources.

Further, such consistent behaviour in at least two observations was a prerequisite for calling a fringe detection positive in all those class *b* sources where the maximum correlated amplitude was only between 3.5 and 4 r.m.s. It can be shown<sup>11</sup> using random noise statistics together with the above checks that at most 1 of the claimed 21 detections can be spurious. As a further check, we again correlated the data after artificially introducing an extra time delay of  $2.5 \mu\text{s}$ , which is equivalent to looking at 'empty sky' because the delay is  $\sim 5$  times the coherence time defined by the system bandwidth of 2 MHz. Of the available 70 sets of observations, in only one case was a peak found on the correlated output which could satisfy all our detection criteria

specified above. Again, this empirical result on 'empty sky' suggests that all the 21 detections in our sample are most probably real.

For most sources, the position angle of the projected baseline changed appreciably between the observations. However, the fringe spacing remained around 0.05 arc s for sources at positive declinations but varied between 0.05 and 0.125 arc s for the southern sources. Two noticeable trends from Table 1 are: the correlated amplitude of a source changed little with position angle and showed no definite tendency to increase with fringe spacing, and the core fractions of the southern sources are not higher than those of the northern sources, though the former were observed at considerably larger fringe spacings. These two points together strongly suggest that all the detected compact components are essentially unresolved even at the smallest fringe spacing used and hence they are smaller than  $\sim 0.02$  arc s in size. We expect these compact components to be associated with the optical nuclei of the sources, as there is not enough evidence that such compact and prominent structures occur in the outer lobes of radio sources. For instance, Broderick and Condon<sup>12</sup> made a sensitive VLBI search at 430 MHz for components smaller than  $\sim 0.03$  arc s in a large sample of 100 extragalactic sources, which also includes some few-arc second sources. They found such compact components, contributing a significant fraction ( $>3\%$ ) of the total flux density, exclusively in those sources which either have a flat radio spectrum or a quasar identification and therefore probably also possess a prominent nuclear radio core. A similar absence of compact hot spots ( $\leq 0.02$  arc s) in the outer lobes has been reported for some few-arc second sources, such as 3C225B and 3C309.1, for which sufficiently detailed observations are now available<sup>13-16</sup>. Note that in recent VLBI work<sup>17</sup> on 35 3CR sources with a fringe spacing of 0.16 arc s at 1.4 GHz, compact components have been detected in the outer lobes of many double sources. However, whenever they were found to be sufficiently strong (emitting  $>5\%$  of the total flux density), these components showed evidence of resolution by the 0.16 arc s beam. In contrast, the compact components found in the present observations at 5 GHz seem to be considerably smaller and their contribution to the total emission is generally much higher than 5% (see Table 1). It therefore seems more appropriate to suppose that our detected compact components in the few-arc second sources are associated with their nuclear regions.

Each of the 30 few-arc second sources in our sample is probably a distant object located at a redshift  $z > 0.3$  (and hence a powerful radio source radiating  $\geq 10^{33}$  erg s<sup>-1</sup> Hz<sup>-1</sup> at 327 MHz). This follows from the analysis of radio source properties by Swarup and Subrahmanya<sup>5</sup> and is also indicated by the optical identifications of these 30 sources (Table 1). Excluding two that lie in crowded fields, seven are identified with blue-stellar objects and hence are probably distant quasars; 18 lie in empty fields and are likely to be galaxies at  $z \geq 0.4$  (refs 18-21). The remaining three sources have galaxy-like counterparts but even the brightest (and probably the nearest) of them is an object of  $m_R \sim 19$  which translates to  $z \sim 0.3$ . These relatively high redshifts of the few-arc second sources should not, however, be systematically any different from the redshifts of the remaining 236 sources (mostly of larger angular size) in the parent sample A. This is because the optical identification rate of 37% among the 30 few-arc second sources is nearly identical to the identification rate of 39% mentioned above for the entire sample A. Consequently, the emission wavelengths of the observed radiation should not be systematically different for the two sets of sources. Among the few-arc second sources, there seems to be no obvious correlation between the presence of an optical identification and of a bright radio nucleus (Table 1). We notice a similar trend in the published VLBI observations of a complete sample of 100 extragalactic radio sources selected from the BDFL catalogue<sup>12</sup>.

Table 1 shows that in 15 of the total 30 few-arc second sources, the radio nucleus accounts for more than a quarter of the total flux density at 5 GHz (in fact, similarly dominant radio

nuclei may exist in a few more of the 30 sources but these would have escaped detection because the sources are so weak that their total flux densities lie well below 100 mJy at 5 GHz). The above result on the fraction of sources with a core fraction  $C_s > 1/4$  can be parametrized by  $F_s(>1/4) \geq 15/30 = 0.5$  and below we compare it with the corresponding values found for four fairly large and well-studied representative samples of extended radio sources again derived from metre wavelength catalogues.

(1) Sample 1 (galaxies): at NRAO, Bridle and Fomalont<sup>22</sup> have mapped a large sample of 4C sources identified with galaxies brighter than 18 mag (double or triple morphology was commonly observed). Considering only those 150 sources with size  $>20$  arc s and lying at  $\delta > 15^\circ$ , we estimate that a sub-arc s component with a core fraction  $C_s > 1/4$  at 5 GHz occurs in only 12 sources. This gives  $F_s(>1/4) = 0.08$ .

(2) Sample 2 (galaxies and quasars): in the 3CR complete sample, 66 sources show a classical double morphology with an established optical counterpart<sup>23</sup>. In only two of them, is a core fraction  $C_s > 1/4$  seen<sup>24</sup>. Thus,  $F_s(>1/4) \sim 0.03$ .

(3) Sample 3 (quasars): at Westerbork, Miley and Hartsuijker<sup>25</sup> have mapped at 5 GHz a sample of 114 4C quasars. Of them, 43 are classified as double with a size  $>20$  arc s and possibly having a compact radio core which is clearly distinguishable from the straddling outer lobes. Of these 43, only seven have  $C_s > 1/4$ . Thus,  $F_s(>1/4) = 0.16$ .

(4) Sample 4 (quasars): at NRAO, Potash and Wardle<sup>26</sup> have mapped a sample of 52 4C quasars at 2.7 and 8.1 GHz, of which 16 are larger than 20 arc s and show a double morphology with a possible central radio core. From these data, we estimate that three of the 16 quasars have  $C_s > 1/4$ . Thus,  $F_s(>1/4) = 0.19$ .

The above comparison shows that in double sources of large angular size, whose axes are mostly expected at large angles from the line of sight, the radio nuclei are much less prominent as compared with those detected in the few-arc second sources by the present VLBI observations. In reality, the contrast is even more striking if one takes into account that the few-arc second sources were selected from a metre wavelength survey and hence  $\sim 80\%$  are likely to be associated with galaxies (see above and refs 4, 18-21, 27), and that the radio nuclei in galaxies are an order of magnitude weaker than those in quasars of the same total luminosity (see ref. 28).

To understand fully the meaning of the very different levels of nuclear radio emission observed in the few-arc second sources and in sources of larger angular extent, one needs to assess the importance of projection in the former case. Generally, few-arc second sources can arise in two ways and depending on the relative strength of these two types among our 30, the present VLBI results can be taken as evidence for either or both of the following, each of which represents an extreme situation:

(1) If all the few-arc second sources are intrinsically normal sized doubles reduced to small angular size because of projection, the observed high core-fraction in them would be consistent with the hypothesis of beaming of the nuclear radio emission along the source axis<sup>1-3</sup>. The implication of such beaming on the large scale structure of double sources has been discussed elsewhere<sup>24</sup>. Note also that the occurrence of beaming in the nuclei of extended radio sources need not conflict with the opposite claim made recently for optically selected quasars<sup>29</sup>, because the entire radio source in these quasars is visualized<sup>29</sup> as being so compact that the relativistic particles have yet to break out of the nuclear cloud of thermal plasma.

(2) Alternatively, the small angular size of few-arc second sources could be due to their being intrinsically small. If so, their physical sizes would only be  $\sim 10$ -50 kpc but they would probably have a double morphology, as is typical for powerful radio sources<sup>6</sup> (high radio luminosities for them were inferred above from their estimated large redshifts  $z \geq 0.3$ ). Such an interpretation would assign to them properties radically different from what is known about powerful radio sources in nearby space, hinting that very strong cosmological effects would have to be present. For instance, at  $z < 0.1$ , intrinsic sizes<sup>30</sup> of

powerful double sources ( $P_{1400} > 10^{32} \text{ erg s}^{-1} \text{ Hz}^{-1}$  for  $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ ) are very rarely, if ever,  $< 200 \text{ kpc}$ . However, if the few-arc second sources are intrinsically small, the detection of very prominent nuclear radio cores in them would mean that the time scale over which the nuclear ratio emission in powerful sources declines markedly, relative to the lobe emission, is comparable with the time needed by the lobes to emerge out of the main body of the parent galaxy.

To distinguish between the above two possibilities the extent to which projection determines their angular sizes needs to be assessed. Some insight into this question can be gained by mapping their arc second structures. Were the projection important, the two lobes might still be distinguishable but they would probably not appear elongated parallel to the line joining them. Note that such a morphology has been observed in the quasar 3C309.1 (a few-arc second source) mapped recently with a sub-arc second beam<sup>16</sup>, but is in contrast to the elongation of the lobes parallel to the source axis, as seen in extended double sources for which projection effects are expected to be minimal.

We thank H. Blaschke, U. Stursberg and W. Alef for help with data processing and R. Porcas for useful discussions. G.K. acknowledges support received from the Alexander-von-Humboldt Foundation.

## Decrease in CO<sub>2</sub> mixing ratio observed in the stratosphere

W. Bischof

Department of Meteorology, University of Stockholm,  
S-10691 Stockholm, Sweden

P. Fabian & R. Borchers

Max-Planck-Institut für Aeronomie, D-3411 Lindau, FRG

**Air samples, collected cryogenically at different heights of the stratosphere, were analysed for carbon dioxide with an IR absorption technique. Supplementary tropospheric air samples were taken aboard commercial airliners. The results reported here show that the CO<sub>2</sub> mixing ratio is not constant with altitude but rather decreases in the stratosphere, by about 7 p.p.m.v., between the tropopause and 33 km. One conclusion is that recently increased concentrations of CO<sub>2</sub> in the troposphere have not propagated far into the stratosphere.**

**Fig. 1** Balloon and aircraft samples taken from 1977 to 1979. Balloon samples: ▲, September 1977; ●, June 1978; ■, 28 June 1979; ○, 9 November 1979. Aircraft samples 27 June 1979: ○, Stockholm; +, Copenhagen descent; ×, Copenhagen ascent; □, Zürich–Copenhagen; △, Zürich. Aircraft samples November 1979: ◆, Copenhagen, 12 November; ▼, Copenhagen, 15 November.

The balloon-borne cryogenic sampler is described elsewhere<sup>1</sup>, together with mid-latitude, vertical profiles of H<sub>2</sub>, CH<sub>4</sub>, CO, N<sub>2</sub>O, CFCl<sub>3</sub> and CF<sub>2</sub>Cl<sub>2</sub> obtained from gas-chromatographic analysis of the samples. CO<sub>2</sub> can also be analysed by gas chromatography, but the total error is of the order of  $\pm 1\%$ , corresponding to  $\sim \pm 3 \text{ p.p.m.v.}$  With the IR absorption technique, however, flask samples can be analysed with a total error of less than  $\pm 0.2 \text{ p.p.m.v.}$ , a figure which already includes the error from the absolute calibration<sup>2</sup>.

For the first set of samples, taken during balloon flights in 1977 and 1978, which had been stored for more than one year, we found that some drifted considerably. In Fig. 1 we plot only the data from those samples which appeared to be stable—those that varied by less than 0.5 p.p.m.v. over a 3-month period. These clearly show that the stratospheric CO<sub>2</sub> mixing ratio is not constant with height but rather decreases with increasing height. This was confirmed by the results from samples collected on 28 June 1979. The CO<sub>2</sub> IR gas analysis was carried out 4 months after the flight. Although two samples whose CO<sub>2</sub> concentration drifted considerably were discarded, an apparently similar vertical profile was obtained from the stable samples. To demonstrate the vertical CO<sub>2</sub> distribution in the troposphere at the same time, supplementary air samples were collected on 27 June aboard commercial airliners, at different mid-latitude locations and different heights, and also analysed for CO<sub>2</sub>. The results, also shown in Fig. 1, demonstrate that the highest CO<sub>2</sub> mixing ratios are observed at the tropopause level, which was at  $\sim 10 \text{ km}$ . The three stratospheric samples taken at 10.6-km altitude, during a Zürich–Copenhagen flight, suggest that the decrease in the CO<sub>2</sub> mixing ratio starts immediately at the tropopause. The decreasing CO<sub>2</sub> content from the tropopause level down, which is also noticeable in Fig. 1, is a result of CO<sub>2</sub> uptake by the vegetation at this time of the year.

The CO<sub>2</sub> mixing ratios analysed from seven stratospheric samples collected during a balloon flight on 9 November 1979, supplemented by five tropospheric samples from 12 and 15 November, fit fairly well with the vertical distribution of carbon dioxide, although some scatter is noticeable. Because no repeated analysis checks could be made for this last set of air

samples, we cannot decide whether or not this scatter is real or due to concentration drifts in some sample containers.

Our results show that the stratospheric  $\text{CO}_2$  mixing ratio decreases from 332 p.p.m.v. at the tropopause to  $\sim 325$  p.p.m.v. at a height of 25 km. These values are related to the Scripps 1959 manometric scale (see ref. 2). Our data do not give any indication of a vertical gradient higher up. This decrease of 7 p.p.m.v. disagrees with results obtained by Volz *et al.*<sup>3</sup>. They found, through gas-chromatographic analysis of stratospheric air samples, a constant  $\text{CO}_2$  mixing ratio of  $\sim 320$  p.p.m.v. for the whole height range discussed here.

Because the presently known photochemical reactions cannot account for the stratospheric  $\text{CO}_2$  decrease we found, this is likely to be the result of long-range transport and exchange between the troposphere and stratosphere. In fact, due to the burning of fossil fuel, the tropospheric  $\text{CO}_2$  mixing ratio increases by  $\sim 1\text{--}1.5$  p.p.m.v. every year<sup>2</sup> and had an annual average for 1979 of 332 p.p.m.v. This man-made increase in tropospheric  $\text{CO}_2$  is gradually propagating upwards with a delay that increases with increasing altitude. The vertical gradient shown in the diagram, which is a result of this slow vertical mixing, suggests a delay of 5–6 yr between the tropopause and an altitude of 25 km.

The stratospheric balloon sampling project was sponsored by the German Federal Ministry of Research and Technology, grant no. FKW-03. The  $\text{CO}_2$  project at Stockholm University is supported by the Swedish SRC.

## Grand unification magnetic monopoles inside the Earth

R. A. Carrigan Jr

Fermi National Accelerator Laboratory, Batavia, Illinois 60510

**Elementary particle grand unification theories admit the possibility of very massive magnetic monopoles, but standard cosmology gives too many poles. Massive monopoles are affected both by gravity and magnetism, requiring reassessment of existing monopole searches. Monopoles inside the Earth would be able to annihilate with each field reversal, thereby giving rise to additional internal heat. This perspective is used to estimate an upper limit for the monopole-to-baryon ratio at accretion of  $10^{-28}$ .**

Grand unification particle theories such as  $\text{SU}(5)$  allow the existence of massive magnetic monopoles<sup>1</sup>. Polyakov and 't Hooft<sup>2,3</sup> observed that theories such as  $\text{SU}(5)$  with an imbedded  $\text{U}(1)$  symmetry could contain a magnetic monopole solution<sup>4,5</sup>. Goddard and Olive<sup>6</sup> noted that this approach can reproduce Dirac charge quantization<sup>7</sup> by using a massive vector boson. Bogomol'nyi<sup>8</sup> has found a lower limit on the monopole mass of  $M > 4M_v/g^2$  where  $M_v$  is the mass of the boson and  $g^2$  is a dimensionless coupling constant. If  $M_v$  is the vector boson of weak interactions,  $g^2$  is equal to  $\alpha$ , and the Bogomol'nyi limit is of the order of  $10^4$  GeV.

Many grand unification theories are characterized by the presence of super heavy bosons with a mass<sup>9,10</sup> of the order of  $M_x = 10^{14}$  GeV. The mass of a grand unification magnetic monopole (GUMM) is set by the Bogomol'nyi limit with the related coupling constant of the order of  $1/50$  (ref. 11), so that GUMMs are expected to have masses of the order of  $10^{16}$  GeV or  $0.02 \mu\text{g}$ .

Such massive particles might have been produced in the big bang in the early Universe. It has been shown<sup>12–14</sup> that for standard cosmology and plausible grand unification models that the number of GUMMs would be close to the number of baryons even now. The evidence is against this in our corner of the Universe. Several ways of circumventing Preskill's paradox have been suggested. These include first-order phase transitions<sup>15</sup>, electric charge non-conservation<sup>16,17</sup>, unusual group structures<sup>18</sup> and cosmological statistical non-equilibrium<sup>19</sup>. The grand unification–standard cosmology system is then faced with a paradox that can be moderated or even turned off but with difficulty. Grand unification remains to be established as a fundamental relevant theory and standard cosmology seems to leave some room for adjustments. However, this paradoxical situation means we need to understand better the limits on the existence of massive magnetic monopoles.

A massive magnetic monopole could be produced either in the big bang or in a cosmic-ray interaction. Bludman and Ruderman<sup>20</sup> have shown that it is not feasible to produce particles with the masses of GUMMs in cosmic ray collisions. A GUMM born in the primordial fireball that survives annihilation can be accelerated to  $10^{11}$  GeV by galactic fields<sup>21,22</sup> of the order of  $3 \times 10^{-6}$  G acting over distances of  $10^{21}$  cm (ref. 23). As these are non-relativistic energies, previous conventional wisdom on energy loss of relativistic monopoles and on transit times must be used with discretion.

No magnetic monopoles have been found<sup>24</sup>. In a typical search, magnetic charges are expected to produce heavy ionization in matter, but for non-relativistic energies the energy loss is smaller<sup>25</sup>. Where timed counters are used, care must be taken. Typically<sup>26</sup> a pole accelerated for 50 cm in an 80-kg field and detected with counters spaced 25-cm apart and a timing window of 20 ns, would give a minimum  $\beta$  of 0.04 and an upper limit for mass that could be detected of  $10^5$  GeV.

A monopole passing through a coil should produce an induced voltage<sup>27</sup>. This technique has been exploited to show that the monopole-to-baryon ratio is  $< 3 \times 10^{-28}$  near the surface of the Moon<sup>28</sup>. As with all other searches this limit is affected by the circumstances of the monopole trapping.

Parker has shown that monopoles would have a profound effect in dissipating and neutralizing large-scale magnetic fields. For relativistic Dirac poles this sets a limit on the monopole-to-baryon ratio for the galactic system of  $2 \times 10^{-26}$ , while for non-relativistic poles it would be around  $10^{-24}$ . Solar and terrestrial field limits are less stringent and the galactic limit is less stringent than the lunar search.

A primordial magnetic monopole is subjected to forces from cosmological magnetic fields, gravitational forces, other magnetic monopoles, and interactions with ordinary electronic matter through processes such as ionization. Many analyses of pole behaviour only consider the magnetic effects. For GUMMs, the force of gravity will approach the effect of cosmic magnetic fields. The gravitational energy acquired by a typical GUMM falling into a galactic disk is  $10^{10}$  GeV while the energy gained in passing through a galactic magnetic field fluxuation (300 light yr) is  $2 \times 10^{10}$  GeV. A GUMM with this energy could go deep into the Earth. The magnetic force at the galaxy is 500 times the gravitational force but the gravitational force acts over a much larger distance. The gravitational energy from solar or terrestrial sources exceeds the energy acquired from the corresponding magnetic field. For a magnetic dipole Earth acting in a repulsive sense (not a realistic approximation here) the magnetic and gravitational forces are in equilibrium at  $R = 0.18 R_e$ . This is well inside the radius of the core ( $R_c = 0.55 R_e$ ).

In a dense material a GUMM will be thermalized and move to an equilibrium position of the magnetic, gravitational, and other forces. In a dipole Earth this would be on a line with the opposite terrestrial magnetic pole and the gravitational centre. The same is true for magnetic fields generated by currents. If the pole is in a fluid it will be able to move freely. In a solid it may have to move by lattice jumps<sup>29</sup>.

Because gravitation forces and magnetic forces are intermingled, one must be cautious about where one looks for GUMMs. A heavy pole that accretes in equilibrium with the material of the Earth will move preferentially closer to the Earth's centre because of the presence of a terrestrial magnetic field. Thus, the Earth's surface is a poor place to look for GUMMs.

The Earth's magnetic field reverses irregularly<sup>23,30</sup> with epochs lasting typically a million years interspersed with occasional events of shorter duration. The reversal takes of the order of 1,000 yr and is turbulent. The Earth's magnetic field is due to a convective dynamo in the fluid core. The dipole field lines flow into the core and then spiral around the Earth's axis of rotation, resulting in larger axial (100 G) than poloidal fluxes (5 G). Further complexity is introduced by convective cells within the dynamo.

When the field reverses, GUMMs of one polarity would move to positions previously held by the opposite polarity. Some of them would pass close enough to opposite sign poles to attract, bind and annihilate, resulting in the release of an extraordinary amount of energy. What, then, would be the contribution of such an energy source to the terrestrial heat inventory?

The heat generation inside the Earth is not completely understood<sup>31</sup>. Heat comes from both gravitational forces and radioactivity. Differentiation processes concentrate radioactive materials selectively in the silicates which form the Earth's crust so that much of the radioactivity is near the surface. Estimates of average heat flow per unit area over the surface area have been revised upwards in the past decade by 20–40%. Uncertainties include the amount of radioactivity, thermal properties of the high-pressure core material, and the contributions of the ocean basins. Clearly, then, understanding the relevant contributions to this heat flow is no easy matter. The average heat flow at the surface is of the order of  $1.5 \times 10^{-6}$  cal cm<sup>-2</sup> s<sup>-1</sup>. The total heat output is  $3 \times 10^{20}$  erg s<sup>-1</sup> ( $2 \times 10^{23}$  GeV s<sup>-1</sup>).

To estimate an upper limit on monopole annihilation as a heat source, we assume that of the order of 25% of the Earth's heat generation could easily come from this source. This corresponds to a heat source of  $5 \times 10^{22}$  GeV s<sup>-1</sup>. For a field reversal every 500,000 yr each reversal must supply  $8 \times 10^{35}$  GeV. If the annihilation energy is perfectly coupled to terrestrial material this requires the annihilation of  $10^{20}$  GUMMs. If the annihilation region is confined to the Earth's core the annihilation event density is  $n_a = 4 \times 10^{-7}$  cm<sup>-3</sup>.

One model to get a monopole density for one polarity,  $n$ , is to assume that the core is uniformly filled with north and south poles. Poles are moving with some relative velocity  $v_D$  as they wander through the liquid core. When they approach within  $r_a$  where the pole-antipole force is sufficiently strong to overcome external forces, they will annihilate, provided the angular momentum between the poles is small enough. The annihilation event density is

$$n_a = \pi r_a^2 v_D t n^2 \quad (1)$$

where  $t$  is the time during which annihilation can occur in the reversal. Initial inhomogeneities would have to be present because the monopoles with opposite polarity would be separated. But, as the reversal proceeds, the equilibrium condition could exist over different smaller regions of the core. The model would still be satisfactory provided  $t$  represented the average time for some region to pass through equilibrium.

For a monopole in equilibrium with the liquid core at a temperature of 4,000 K, the thermal velocity is of the order of  $10^{-2}$  cm s<sup>-1</sup>, as is the average mass drift velocity. But for an axial field of 100 G, the characteristic monopole velocity might be  $10^5$  cm s<sup>-1</sup> based on extrapolating the Ahlen energy loss formula<sup>25</sup> to low  $\beta$  values. With the complex field geometry fully on, monopoles would move to equilibrium positions probably near the surface of the solid core or the inner surface of the mantle in  $\sim 1$  yr. If the reversal is turbulent, though, monopoles might slow substantially for some period even as they moved to regions where field lines had moved in again. At a velocity of

$10^{-2}$  cm s<sup>-1</sup> the time to produce a homogeneous condition is of the order of  $10^{10}$  s.

The capture distance,  $r_a$ , is sensitive to gravity, the terrestrial magnetic field and relative pole velocity. For characteristic forces that would be present ( $10^{-5}$  dyne), a plausible capture distance would be  $10^{-5}$  cm.

For these conditions, the monopole density in the core to produce one-quarter of the Earth's heat is  $n = 1.5 \times 10^{-3}$  cm<sup>-3</sup>. This is equivalent to an upper limit on the monopole-to-baryon ratio at accretion of  $2 \times 10^{-28}$ . The baryon number is taken for the entire Earth rather than the core alone as it is presumed that monopoles were differentially attracted to the core. The pole density could not be too much larger because the poles would cancel the Earth's field. Field dissipation due to magnetic currents is less of a constraint.

This limit depends on the pole mass. Turbulence and inhomogeneities could also change the limit. It is difficult to attach any estimate of accuracy to a limit based on such a speculative mechanism. Nevertheless, the picture suggests that the upper limit on the monopole-to-baryon ratio in the Earth is extremely small and consistent with the upper limit on the ratio observed at the surface of the Moon. This strengthens the Preskill paradox and indicates that the grand unification-standard cosmology-GUMM collection picture must break down at some point.

A GUMM density near this limit would be sufficient to supply energy for of the order of  $10^4$  field reversals (the age of the Earth). Such a density would degrade the Earth's field by 10% with the details depending on the equilibrium configuration. For a constant dynamo strength over the life of the Earth the average net field would rise with time as the monopoles annihilated.

There has been little consideration of the details of annihilation of GUMM pairs but they would probably annihilate rapidly into many particles with energies of  $10^{14}$  GeV, some of which would decay quickly into muons and neutrinos. Muons at these energies lose nearly all of their energy by radiation rather than ionization<sup>33</sup> so that the energy is dissipated within 20 km of the annihilation point. The neutrino cross-section<sup>34</sup> is expected to be of the order of  $\sigma_\nu = 10^{-34}$  cm<sup>2</sup>, so that a substantial fraction of the neutrinos would interact in the Earth. During a field reversal much of the GUMM mass would be converted to heat in the core. Heat transfer times from the core are of the order of the age of the Earth so that the individual field reversals would be averaged out. Some portion of the neutrino energy deposited in a layer close to the surface (roughly 10 km) would appear as an effective heat pulse during a field reversal. This is only 0.1% of the neutrino energy and substantially less of the total but appears in 1/500 the time so that it might constitute a thermal spike of the order of 0.01–0.1 of the average heat flow. This spike seems to be insufficient to have an effect on the polar ice caps<sup>35</sup>.

The Moon has no dipole-like field<sup>36</sup>, but a field of 0.05–1 G would have been necessary to produce the magnetization<sup>37</sup>. It is difficult to model a lunar dynamo that would have produced the field<sup>23</sup>. If the Moon accreted from a mix with a GUMM-to-baryon ratio five times larger than the upper limit earlier suggested for the Earth and the GUMMs differentiated out into opposite poles during the process their presence could explain a slowly decaying relic field of the order of 0.1 G. Some mechanism such as an external field from the Earth or the solar wind would have been needed to establish the north-south separation.

Thus even small admixtures of GUMMs would produce noticeable changes in planetary conditions. On the other hand the search for massive primordial monopoles should continue. Possibilities might include meteors from the cores of large asteroid bodies. Perhaps some reconsideration should be given to tracks in emulsion purported to come from one-third of Dirac charge monopoles in experiments on meteorites<sup>38</sup>. These could have been due to massive, slowly moving monopoles with concomitantly smaller energy loss. A later experiment was more sensitive but not to GUMM masses.

## Authigenic dolomite on marble surface

M. Del Monte

Istituto di Geologia, Università di Bologna, 40126 Bologna, Italy

C. Sabbioni

Laboratorio FISBAT-CNR, 40126 Bologna, Italy

The formation of dolomite remains controversial. Various hypotheses have been proposed, including primary precipitation from seawater, authigenesis or penecontemporaneous alteration of  $\text{CaCO}_3$  by seawater, and postdiagenetic secondary replacement of  $\text{CaCO}_3$  by groundwater, connate water, or other solutions. Although the existence of authigenic dolomite in recent sediments has been confirmed<sup>1-3</sup>, all attempts to synthesize ordered dolomite at temperatures of sedimentary environments have failed<sup>4</sup>. It has been suggested that organic material<sup>5,6</sup> and clay minerals<sup>7,8</sup> may be important in the formation mechanism of dolomite. Here we present evidence that authigenic dolomite is formed on marble surfaces exposed to urban atmospheres. This discovery suggests that a relatively short period of time (of the order of a century) is actually required for dolomite formation in the natural system described here.

We have studied for many years the effects of the atmosphere on the deterioration of building stones. Samples from San Petronio (fourteenth century) and other more recent buildings in Bologna (Northern Italy) have been examined. Analyses on many altered layers found on limestone and marble surfaces have shown the following parageneses:

- (1) authigenic dolomite and calcite, quartz, K-feldspar;
- (2) authigenic calcite, quartz, K-feldspar;
- (3) authigenic gypsum and calcite, K-feldspar, Na-feldspar, graphite;

- (4) authigenic gypsum, quartz, K-feldspar, graphite.

The thickness of the altered layer varies between <1 mm to several mm (Fig. 1).

The variation in the mineralogical parageneses of the altered layer is outlined in Fig. 2. The dolomite clearly prevails in the external layer (A) and decreases progressively from the outside towards the inside until it disappears on contact with the unaltered rock. In the samples where it is only present in traces it is exclusively observed in the superficial layer.

Representative X-ray diffraction analyses (XRD) of samples of calcite and dolomite are shown in Fig. 3. Our results indicate that: (1) in layers A, B, C and D the dolomite presents a slight excess of calcium<sup>12</sup> ( $\text{Ca}_{53}\text{Mg}_{47}$ ) and the calcite shows a  $\text{MgCO}_3$  mole content of 2%; (2) the calcite in the original marble has also a 2 mole %  $\text{MgCO}_3$ ; (3) in the layer where only the calcite precipitates, that is in the sample of the second paragenesis, a high-Mg calcite ( $\text{Ca}_{90}\text{Mg}_{10}$ ) is present. The error in the determination is <1 mole.

The XRD analyses of marble samples dissolved in a 2% solution of acetic acid show that dolomite is not present in the unaltered rock. Sedimentation of dolomite on the surfaces observed as wind-blown dust seems unlikely as then dolomite should also be found in the other parageneses as occurs for quartz and K-feldspar, which seem to be derived from soil erosion. This observation together with optical analyses which show euhedral or subhedral forms and intergrowth texture (Fig. 1) excludes this origin. Nearly stoichiometric calcite was observed alongside dolomite. This phenomenon together with the absence of magnesian calcites means that a metasomatic origin can be excluded. These observations lead us to think that the

**Fig. 1** The altered layer consists of rhombohedral crystals of dolomite and calcite, often twins, with greater dimensions (5–10  $\mu\text{m}$ ) than the crystals of calcite in the unaltered marble. The porosity of the altered layer is high. It is impossible to discriminate calcite from dolomite by optical analysis, but X-ray analyses show that dolomite prevails in the outer layer. *a*, Thin section, Nicols  $\times$ ,  $\times 100$ ; *b*, scanning electron microscopy (SEM),  $\times 1,000$ ; *c*, SEM,  $\times 3,000$ .

**Fig. 2** Schematic diagram of the mineralogical concentrations of the altered layer. The altered layer is of an average thickness of 1 mm. For each area the samples were taken successively A, B, C, D and each were 200–300  $\mu\text{m}$  thick. Quartz and K-feldspar percentages were determined after dissolution of the samples in acetic acid.

dolomite is formed by direct crystallization from aqueous solution. The unaltered rock contains between 0.25 and 0.30% Mg. We think that the Mg in our system does not derive exclusively from the dissolution of the underlying rock, but also from the washing away of the surrounding area. Besides, there is evidence<sup>9</sup> (even though our thermodynamic and chemical conditions differ) of a mobilization of the Mg ion in the solid state, which could affect a limited thickness of the underlying rock in a way which is difficult to evaluate. Quantitative analyses by atomic absorption spectrometry (AAS) of bulk samples of the altered layer have been performed. The presence of elements such as Zn ( $320 \pm 15$  p.p.m.), Cu ( $156 \pm 8$  p.p.m.), V ( $25 \pm 1$  p.p.m.) and Pb ( $20 \pm 2$  p.p.m.), which are absent in the original rock was detected. These elements are evidence of the contribution made by atmospheric particulate. Mg is associated mainly with inorganic salts in coal fly-ash (1,000–10,000 p.p.m.), industrial dust (100–1,000 p.p.m.) and sea spray (3.7%)<sup>10</sup>. Particulate transport phenomena and deposition effects cause serious difficulties in determining an average Mg concentration in our system.

It has been thought<sup>4,11</sup> that a high ratio of Mg/Ca favours the precipitation of dolomite, but this does not seem to be true in our case. However, the circulating solution is being analysed. Moreover the part played by pH, clay minerals and algae in the origin of dolomite must be considered. In none of the samples that we analysed, were dolomite and gypsum present at the same time. Because the hydration of  $\text{SO}_2$  and its oxidation in sulphuric acid produces a lowering of pH in solution, we agree that the formation<sup>5</sup> of dolomite is favoured by a high pH level.

The insoluble residues of some dolomite samples dissolved in 2% acetic acid show either no or only minor quantities of clay minerals. Thus no relationship between clay minerals and dolomite was detected which accords with the results obtained by Lumsden<sup>8</sup>. The presence of algae (*Gleocapsa* sp. and lichen *soredium*) and Basidiomycetes and Ascomycetes spores were observed.

Microclimatic conditions (temperature and humidity) led us to consider the possibility of the local reproduction of these microorganisms with consequent chemical alteration of the medium.

We have shown that authigenic dolomite is present in a different environment from those reported previously, at low (0–50°C) temperatures at one atmosphere with a low Mg/Ca ratio and no clay minerals present. Furthermore the period of formation is fairly short. The upper limit is 500 yr and is even

lower if the effects of restoration carried out subsequently and the presence in the altered layer of elements like Pb, Zn, V, Cu, resulting from industrial development over the past few decades are considered. Dolomite crystals show dimensions up to 10  $\mu\text{m}$ , which together with a low time period of formation suggests a high growth rate. A model for the formation of the altered layer could be: water vapour condenses on the surface and penetrates the porous altered layer. The less porous unaltered rock forming a discontinuity in the system favours an accumulation of water at the interface of the altered and unaltered rock. Here the transformation of the carbonates by the various elements dissolved in

**Fig. 3** X-ray Cu-K $\alpha$  diffraction patterns of: a, altered layer dolomite-calcite; b, unaltered marble; c, altered layer with only precipitation of calcite. The composition of dolomite (D) and calcite (C) was determined by the position of the  $d$  (104). Fluorite (F:  $d_{111}$ ) and quartz (Q:  $d_{101}$ ) were used as internal standards as their peaks fall reasonably close to the main calcite peak.

the water takes place. The growth of crust occurs in an inward direction so that the altered layers of more recent formation are in contact with the unaltered rock. As this phenomenon proceeds the formation of a protecting coating on the surface which reduce the chemical activity of the rock, or the detachment of the altered layer occurs.

We thank O. Vittori and E. Bonatti for helpful discussions, E. MacLoren for creating interest in the aspect of the dolomite formation, and P. Mandrioli for biological analyses. This work was supported, by a grant of Piano Finalizzato Promozione della qualità dell'ambiente CNR.

## The Welsh 'geosyncline' of the Silurian was a fore-arc basin

H. Okada

Department of Geosciences, Shizuoka University, Shizuoka, Japan

A. J. Smith

Department of Geology, Bedford College, University of London, London NW1 4NS, UK

The Welsh 'geosyncline'<sup>1</sup>, an example of the classic geosyncline, has often been viewed in terms of plate tectonics as a Japan Sea-type marginal sea<sup>2-15</sup>. It is generally agreed that in the Welsh area during Cambrian and Ordovician times, Anglesey, with its north-east and south-west extensions, was an island arc complex with a trench to the north-west, the trench being accompanied by a south-east dipping subduction zone which caused the Ordovician volcanism of Wales<sup>2,5,10-14</sup>. Some authors believe that the Welsh region was the site of a back-arc tensional basin at the time of Ordovician volcanism. We believe that in Silurian times the subduction zone migrated landwards, that is southeastwards, due to tectonic erosion<sup>16</sup>, a process which has been implied for the modern Japan Trench<sup>17</sup>. Here, we compare the Welsh Silurian Basin with the modern Japan Sea and the sedimentary basins of the Pacific offshore of Japan, and conclude that a different interpretation is possible, that the Silurian Basin could have been a fore-arc basin.

In south-west Japan, between 132°E and 136°E in the vicinity of the Nankai Trough, the present subduction started at the earliest some 5 Myr ago<sup>18</sup> and the subducting slab is thought to have now reached a depth of only about 50 km (ref. 19). Because the subduction is still young, there has been no Quaternary volcanism in this segment of the Japanese islands. We believe a similar situation existed in the Welsh region in the Silurian. In middle to late Llandovery times, the renewed subduction following a landward migration of the subduction

zone caused compressional uplift of North Wales and the adjacent Irish Sea Tectonic High. Such uplifts can be compared with the Oyashio ancient landmass postulated at the trench-slope break of the modern Japan Trench (Fig. 1)<sup>20</sup>. At this stage the angle of the newly subducting slab was too small and the subducting edge of the slab too shallow to allow arc volcanism. Only by Wenlock times was volcanism again possible in Wales and adjacent areas (Fig. 1).

If the Welsh Basin of the Silurian could be represented as the Japan Sea-type marginal basin, then it should be characterized somewhere by tholeiitic ocean-floor basement and by ridge and trough features formed by rifting. No such characteristic features have yet been discovered. Conversely, the major faults found in Wales and the Welsh Borderland such as the Bala and Church Stretton Faults, are not dissimilar from those found in

**Fig. 4** Seismic profiles of the Japan Trench transect at 40°N *a*, General structural profile, redrawn from ref. 20. Numbers along the top of *a* refer to DSDP sites of Leg 56/57; indicated depth in km. *b*, Detailed seismic section of the fore-arc basin in *a* showing landward migration of depocentres<sup>17</sup>. Fig. 5 Schematic diagrams showing landward migrations of depocentres of major Silurian turbidite sequences in Wales.

fore-arc basins—see, for example, those of the Sumatran continental margin<sup>21</sup>.

It seems possible to compare closely the Silurian Welsh Basin with modern arc-trench gap basins or fore-arc basins in several ways: tectonic position, volcanicity or its absence, the scale, size and shape of the basin and sedimentation types, styles and patterns. To emphasize this, we consider some fore-arc basins behind, that is landward, of the Nankai Trough (Figs 2, 3)<sup>22</sup> and the Japan Trench. The Tosa Basin, for example, is about 80 km across and 200 km long and accommodates late Miocene to Quaternary sediments to more than 1 km in thickness. These sediments are characteristically terrigenous turbidites and moreover they exhibit the tendency of depocentres to migrate inwards or landwards with time as the trench-slope break tectonic high is uplifted (see Fig. 4, which illustrates the Japan Trench situation). A similar trend of migration of depocentres is seen in the succeeding stages of the Silurian in the Welsh geosyncline (Fig. 5).

Changes in the subduction angles inferred for the Welsh geosyncline can be explained by Kanamori's<sup>23</sup> cyclic evolutionary model of oceanic plate subduction. According to Niitsuma's estimates<sup>24</sup>, the time length of unit cycles of plate subduction in the Japanese Neogene sequences is 10–20 Myr. Such an interval fits well with those of the Welsh Basin.

Such a multiplicity of coincidences between the fore-arc situation as has existed from early Neogene times on the Pacific side of Japan and the evidence from the Silurian rocks of Wales at least demands serious consideration of the conclusion that the Silurian Basin of Wales could have been a fore-arc basin.

## Age and magmatic evolution of Stromboli volcano from $^{230}\text{Th}$ – $^{238}\text{U}$ disequilibrium data

Michel Condomines & C. J. Allegre

Laboratoire de Géochimie et Cosmochimie, Département des Sciences de la Terre, 4, Place Jussieu, 75230 Paris Cedex 05, France

The Eolian archipelago is one of the two active volcanic arcs in the Mediterranean. Of its seven islands, only Vulcano and Stromboli have erupted recently. Stromboli is well known for its continuous explosive activity. Whereas the relative ages of volcanism are fairly well known from stratigraphical methods<sup>1,2</sup> there has been little absolute dating. Precise age determinations for the different islands are, however, necessary to study the evolution of the whole Eolian arc volcanism, notably the transition from calc-alkaline series to shoshonitic series<sup>3,4</sup>. We report here the age determination of lavas on Stromboli using a method based on the radioactive disequilibrium  $^{230}\text{Th}/^{238}\text{U}$  applied to volcanic rocks<sup>5–7</sup>. The analytical techniques have been described elsewhere<sup>8</sup>. The activity ratio ( $^{230}\text{Th}/^{232}\text{Th}$ ) is determined through  $\alpha$  spectrometry and the U/Th ratio through isotopic dilution and mass spectrometry.

Stromboli Island can be divided into two parts, an older one to the east and a western, younger part to which the active craters of Stromboli belong (Fig. 1). The oldest part comprises three main formations<sup>9</sup>: (1) a basal pyroclastic complex with interstratified lava flows outcropping at the bottom of canyons and on the east coast (La Petrazza); (2) an intermediate complex made up of scoria and lava flows lying unconformably on the previous complex in the north-east; and (3) an upper complex or Vancori complex (lava flows and sills, tuffs in its uppermost part) which still forms the actual top of the volcano. The lavas of these old complexes belong to the calc-alkaline series and most are either K-rich andesites or Al-rich basalts<sup>4,8</sup>. However, some rare shoshonites have also been observed<sup>9</sup>.

The younger, western part comprises several formations made of lava flows and scoria. The 'Sciara del Fuoco' consists of superimposed historical flows running all the way from the uppermost, active craters down to the sea. The lava from this young area are shoshonitic with a  $\text{SiO}_2$  content usually in the range 50–53%, a variable but high  $\text{K}_2\text{O}$  content (up to 4% or more) and a  $\text{K}_2\text{O}/\text{Na}_2\text{O}$  ratio of  $\sim 1$  (refs 4, 10).

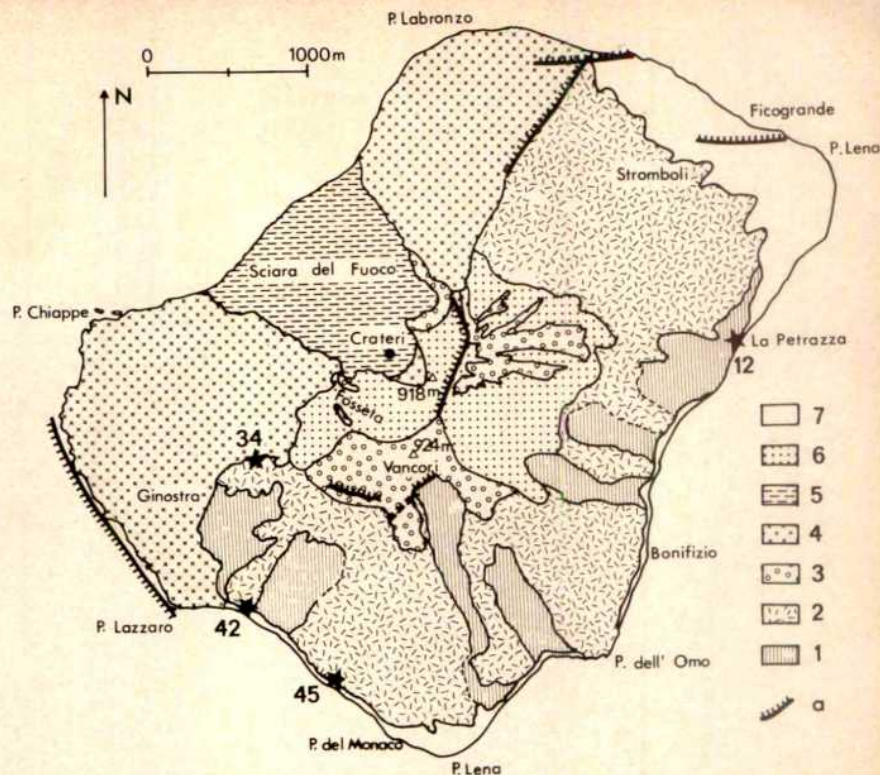

The samples analysed all come from the older eastern region of the island (Fig. 1). Specimen number 12 is from the oldest part of the basal complex around La Petrazza; the other specimens are from the intermediate complex on the south-west coast of the island (Stb 42, 45), and from the slope of the volcano itself (Stb 34; 400-m altitude). Samples Stb 12, 34 and 45 are K-rich andesites whereas Stb 42 is a Si-poor andesite according to Taylor's terminology<sup>11</sup> (F. Barberi, personal communication).

Analytical data and petrographical descriptions are given in Table 1: U and Th contents (Th from  $\sim 10$  to  $\sim 20$  p.p.m.) agree with other Th and U data<sup>12,13</sup> on volcanics from the Stromboli calc-alkaline series. Our data confirm that these series have a higher content of hygromagmatophile elements than do the classic calc-alkaline series. On the ( $^{230}\text{Th}/^{232}\text{Th}$ ), ( $^{238}\text{U}/^{232}\text{Th}$ ) activity-ratio diagram (Fig. 2a) representative whole-rock values fall to the left of the equiline (first bisectrice) which indicates a ( $^{230}\text{Th}/^{238}\text{U}$ ) disequilibrium ratio of  $>1$ .

In an activity-ratio diagram, representative data for minerals from a volcanic rock must fit an isochron of slope  $(1 - e^{-\lambda t})$  thereby giving the age  $t$  of the rock. The intersection between the isochron and the equiline gives the initial ratio ( $^{230}\text{Th}/^{232}\text{Th}$ )<sub>0</sub>.

**Fig. 1** Geological map of Stromboli (after ref. 8): 1, oldest complex (calc-alkaline series); 2, intermediate complex (calc-alkaline series); 3, Vancori complex (calc-alkaline series); 4, young shoshonitic volcanics; 5, Sciara del Fuoco; 6, present cinder cover; 7, alluvions and reworked volcanics; a, faults or ancient caldera edges.

The results of internal isochrone dating on samples Stb 12, 42 and 34 are plotted in Fig. 2. The most important mineral for this type of dating is titanomagnetite because of its higher Th/U fractionation relative to the whole rock (as we pointed out in our studies on lavas from Costa Rica and Etna<sup>5,6</sup>). Nevertheless, for

\* Stb 12: K-rich andesite with zoned plagioclase phenocrysts rich in glass inclusions, clinopyroxene, orthopyroxene and magnetite. The groundmass is made of plagioclase, pyroxene and magnetite microliths. Apatite is also present as needles in plagioclase.

† Stb 42: Si-poor, K-rich andesite with olivine, clinopyroxene and plagioclase (rich in glass and pyroxene inclusions) phenocrysts and magnetite microphenocrysts. The groundmass consists primarily of plagioclase and pyroxene microliths.

‡ Stb 34: K-rich andesite with zoned plagioclase phenocrysts rich in inclusions, clinopyroxene, orthopyroxene, biotite and magnetite in a groundmass of brown glass with tiny plagioclase and pyroxene microliths. Apatite is abundant as inclusions in plagioclase and pyroxenes.

§ Activity ratios: standard error on  $(^{238}\text{U}/^{232}\text{Th})$  is estimated at 1%. The error on  $(^{230}\text{Th}/^{232}\text{Th})$  is the  $\alpha$ -counting error ( $1\sigma$ ).

samples Stb 12 and 42, this fractionation occurs in the opposite direction, that is Th/U for magnetite is greater than for the total rock. For Stb 34 fractionation is 'normal'.

The age of Petrazza lava (Stb 12) from the eastern basal complex is  $\sim 156,000$  yr ( $^{+45,000}_{-32,000}$ ) and its initial ratio close to 1.16. The lack of precision on dating this lava is due to its great age and also, and mostly, to moderate Th/U fractionation between the different minerals and the whole rock. The age of sample Stb 42 from the intermediate complex on the southwestern coast is  $61,500$  yr ( $\pm 6,500$ ) and its initial ratio  $(^{230}\text{Th}/^{232}\text{Th})_0$  0.880 ( $\pm 0.015$ ). The age of sample Stb 34 from the upper part of the intermediate complex is  $35,000$  yr ( $\pm 9,000$ ) and its initial ratio  $1.084$  ( $\pm 0.005$ ).

These ages agree with the relative stratigraphical position of the different lava flows and can be used to infer a general pattern for the chronology of Stromboli volcanism: the oldest-emerged part of the island is at least  $160,000$  yr old, the formation of the intermediate complex probably started at least  $60,000$  yr ago and lasted until  $\sim 30,000$  yr ago. The Vancori complex was then formed, followed by the younger western part of the island.

The transition to shoshonitic volcanism thus occurred  $< 35,000$  yr ago. Barberi *et al.*<sup>4</sup> and Keller<sup>3</sup> consider that this significant transition corresponds to an important change in the subduction process underneath the Eolian arc.  $\text{K}_2\text{O}$ -rich shoshonitic lava could result from fast subduction of the lithosphere<sup>4</sup> or from the presence of an isolated fragment of lithosphere sinking into the mantle<sup>3</sup>. The transition to shoshonitic volcanism must, then, be synchronous along to the strike of the subducting lithosphere. Seismic data show a  $50$ – $60^\circ$  dip towards WNW (refs 14, 15), and Vulcano and Stromboli should thus be in a similar position relative to the subduction zone. Unfortunately, the age of early shoshonitic volcanism for Vulcano has not yet been exactly determined (though it is probably  $< 100,000$  yr (ref. 3)). Our data put limitations on this model and will eventually allow age correlations with neighbouring islands of the Eolian archipelago.

There are too few petrographical and chemical data for older lava from Stromboli to allow a detailed study of magmatic evolution of this island; however, the  $^{230}\text{Th}$ – $^{238}\text{U}$  disequilibrium method can be used to determine the main steps. Indeed, the study of the variation throughout time of the initial ratio  $(^{230}\text{Th}/^{232}\text{Th})_0$  for lavas gives valuable information<sup>5</sup>.

Fig. 2 Isochron diagram for: a, sample Stb 12; b, samples Stb 42 (●) and 34 (○).

When lavas derive from deep magma through evolution in a chemically closed system since a certain time  $T$  (the age of magma isolation), their initial ratios obey the following equation<sup>5</sup>:

$$\left(\frac{^{230}\text{Th}}{^{232}\text{Th}}\right)_0 = \left[\left(\frac{^{230}\text{Th}}{^{232}\text{Th}}\right)_{M_0} - \left(\frac{^{238}\text{U}}{^{232}\text{Th}}\right)_M e^{-\lambda T} + \left(\frac{^{238}\text{U}}{^{232}\text{Th}}\right)_M\right]$$

where  $t$  is the age of lava and  $(^{238}\text{U}/^{232}\text{Th})_M$  and  $(^{230}\text{Th}/^{232}\text{Th})_{M_0}$  the initial ratios of the deep magma. This relation is valid as long as the  $(^{238}\text{U}/^{232}\text{Th})_M$  ratio remains the same throughout fractional crystallization; which is probably the case for such hygromagmatophile elements except, perhaps, for the products resulting from late differentiation.

Indeed, Th/U ratios for calc-alkaline series seem to remain constant. Figure 3 shows Th and U values plotted for our samples as well as those of Guillard<sup>13</sup> for calc-alkaline and shoshonitic series and those determined by Capaldi *et al.*<sup>16,17</sup> for recent Stromboli lavas. On such a diagram, the two series can be readily differentiated on the basis of their Th/U ratios, ~4 for the calc-alkaline series and ~6.5 for the shoshonitic series, which indicates that the primary magma for the two series seems to be different.

Considering the hypothesis that the  $(^{238}\text{U}/^{232}\text{Th})_M$  ratio of the deep primary magma has not been affected during fractional crystallization, one can use the above equation to study the evolution of initial ratios in a  $(^{230}\text{Th}/^{232}\text{Th})_0 - e^{-\lambda T}$  diagram. Representative data for lavas derived from the same deep magma evolving in a chemically closed system must fit a straight line of slope  $[(^{230}\text{Th}/^{232}\text{Th})_{M_0} - (^{238}\text{U}/^{232}\text{Th})_M]e^{-\lambda T}$ , and knowing the position of a lava on such a diagram and the  $(^{238}\text{U}/^{232}\text{Th})_M$  ratio of the deep magma, we can then determine the evolution line for the initial ratios and find out whether other dated lavas belong to the same series—whether they derive from the same deep magma. This method has been used in Fig. 4: samples Stb 12 (156,000 yr) and 42 (61,500 yr) may belong to the same series whereas Stb 34 (35,000 yr) and present lavas from Stromboli seem to have a different origin. Thus, we have to distinguish at least three series:

- (1) A calc-alkaline series starting at least 160,000 yr BP and lasting until about 60,000 yr BP.
- (2) Another younger calc-alkaline series from 60,000 yr BP to <35,000 yr BP. The primary magma of this series seems to be identical with the previous series, the  $(^{230}\text{Th}/^{232}\text{Th})_{M_0}$  ratios being very close.
- (3) The present shoshonitic series for which Th/U ratio is different from that of older shoshonites and would even be

Fig. 3 Th/U diagram for Stromboli lavas: ▲, △, our data; ●, Guillard's data<sup>13</sup>; ✦, Capaldi *et al.*'s data<sup>16,17</sup>.

Fig. 4  $(^{230}\text{Th}/^{232}\text{Th})_0$ - $e^{\lambda t}$  diagram (see text for explanation).

closer to that of calc-alkaline series (Fig. 3). This series would obviously be derived from an initial magma different from that of the calc-alkaline series as their  $(^{230}\text{Th}/^{232}\text{Th})_0$  ratio is much lower (Fig. 4). Besides, the older shoshonites with high Th/U ratios could belong to an intermediate series not shown on Fig. 4.

Samples Stb 12 and 42 and sample Stb 34 which belong to two different series also have opposite Th/U fractionation trends for magnetite compared with the whole rock. This could be due to different crystallization conditions where oxygen fugacity could have an important role (in preparation). This parameter may explain differences between fractional crystallization of the calc-alkaline series and of the shoshonitic series<sup>4,18</sup>.

The series defined above are based on the hypothesis of evolution in a chemically closed system of a deep magma successively feeding the dated eruptions. This deep magma can be isolated in a zone where it generated through partial melting, for example, at the top of the subducting lithospheric plate, or at an intermediate level.

The magma has probably not evolved in a superficial closed-system magma chamber for several tens of thousand years. If it had, then the initial ratio evolution for a given series would be correlated with the differentiation degree of lava, whereas there seem to be several cycles of differentiation, for calc-alkaline series, for example, slightly differentiated lavas alternating with more evolved ones<sup>5</sup>. Therefore, there may have been several reinjections of primary magma into the chamber but the basic magma added could not have the same  $(^{230}\text{Th}/^{232}\text{Th})_0$  ratio because the reduction of  $(^{230}\text{Th}/^{232}\text{Th})_0$  initial ratios would thus be much lower than that actually calculated for the oldest calc-alkaline series, for example. The evolution curve of  $(^{230}\text{Th}/^{232}\text{Th})_0$  would be above the line corresponding to the evolution in a closed system (Fig. 4a). If  $(^{230}\text{Th}/^{232}\text{Th})_0$  ratios variations actually correspond to the evolution line for a closed system, it implies a really deep magma evolving as a chemically closed system with a  $(^{230}\text{Th}/^{232}\text{Th})_0$  ratio decreasing with time and imposing the general variation of the  $(^{230}\text{Th}/^{232}\text{Th})_0$  ratios. The successive reinjection-differentiation cycles would thus be represented by straight segments on the evolution line representing the deep magma evolution (Fig. 4).

The proposed model would thus be: a deep permanent magma evolving as a closed system and feeding through successive reinjections one or several superficial magma chambers, where the main differentiation would take place through fractional crystallization. If this model were verified, there would be important geodynamic implications for the subduction beneath the Eolian arc and for the size of the deep magma reservoirs relative to subduction rates. The problem of calc-alkaline to shoshonitic volcanism transition cannot be solved here because of the lack of data especially on the older shoshonites. We have

shown that shoshonitic series seem to generate from an initial magma different from the calc-alkaline series primary magma which has a higher  $(^{230}\text{Th}/^{232}\text{Th})_0$  ratio. Two hypotheses can be proposed for the origin of this magma: either it comes from a source region different from that of the calc-alkaline primary magma, with a different Th/U ratio, or it results from a modification of the calc-alkaline series primary magma through a more or less complex contamination process. A contamination by relatively high Th/U and low  $(^{230}\text{Th}/^{232}\text{Th})_0$  crust could explain the transition to ancient shoshonites. But there is no evidence for continental type crust underneath the Stromboli volcano, whereas such evidence does exist for other islands in the Eolian arc<sup>1</sup>. Dupuy *et al.*<sup>19</sup> use a fluid-transfer mechanism to explain the important enrichment of shoshonitic magma in hygromagmatophile elements such as K, U and Th. Detailed studies on ancient shoshonites might help solve the problem of their origin. In this respect Th/U ratio measurements and determination of initial  $(^{230}\text{Th}/^{232}\text{Th})_0$  ratios would then be of great interest.

We thank F. Barberi and M. Rosi for samples, and Claude Mercier for the English translation of the manuscript.

## Prehistoric shell assemblages from Franchthi Cave and evolution of the adjacent coastal zone

Judith C. Shackleton

Tjeerd H. van Andel

Geology Department, Stanford University, Stanford, California 94305

Franchthi Cave, Greece, virtually continuously occupied from the late Palaeolithic to the Final Neolithic<sup>1</sup>, is situated at the entrance to Koiláda Bay on the Gulf of Argos, where the sea meets a steep rocky shore just outside the cave entrance (Fig. 1). The deposits of the cave reveal much evidence of man's use of marine resources. For much of the occupational history of the cave, however, the shore was actually quite far away due to the glacial lowering of sea level, for example, 6-7 km during the latest Palaeolithic. Perhaps this is why the earliest deposits examined contain little shell material. A second phase has a mixed shell assemblage of short duration (Fig. 2) but a third one from the late Mesolithic has abundant shell remains dominated by a single species. We show here that these shell assemblages reflect environmental changes resulting from the rising post-glacial sea level.

**Fig. 1** Shoreline positions (yr BP) for the Franchthi area during the late Pleistocene and early Holocene. Based on contours prepared from British Admiralty chart 1518/1954. Data point spacing gives a contour position uncertainty of about  $\pm 200$  m. Sea-level rise curve uncertainty produces a shoreline position uncertainty of 200–500 m. Dashed arrows are streams. Solid lines are seismic reflection traverses and arrow indicates a submerged bar after ref. 6.

From ~9,000 to 8,000 yr BP the inhabitants collected mainly *Cyclope neritea*<sup>2</sup>, a small (~15 mm) species which lives in the littoral zone near the mud surface and also flourishes in brackish water. It is gregarious and a carnivore. Although small it is easy to catch because it occurs in large numbers in very shallow water<sup>3</sup> and can be attracted with bait (M. Bishop, personal communication). It might be eaten raw or as a soup. At about 8,000 yr BP this assemblage is abruptly replaced by another, dominated by *Cerithium vulgatum*<sup>2</sup>, a rock-dweller.

Although the ethnographical evidence provides instances of hunter-gatherers choosing to go long distances to collect delicacies<sup>4</sup>, this behaviour is the exception. Whatever the reason for the change in shell assemblages, we have adopted the view that a group will normally harvest a resource because it is accessible. We also assume that a change in economic or social behaviour may be triggered by environmental factors<sup>5</sup>. Obviously, both changes in shell composition could have been caused by various factors but here we discuss them in terms of an environmental/economic approach. Our interpretation rests on the fact that the post-glacial sea-level rise beginning 17,000 yr ago created a succession of coastal environments which must have influenced the lives of the inhabitants of Franchthi Cave.

There are two explanations for the dominance of *Cyclope* and its sudden replacement around 8,000 yr BP by the *Cerithium* assemblage (Fig. 2). First, *Cyclope* might have flourished on extensive, very shallow and sheltered nearshore flats near the cave. Such an environment might have existed temporarily during the early Holocene. Further migration of the shore into the bay and establishment of present conditions could have eliminated the species. Simultaneously, the advance of the sea produced rocky shores north of the cave, 2–3 km away, where *Cerithium* could be collected instead. Alternatively, the mouth of the river then flowing seaward between Franchthi and the island opposite<sup>6</sup> might have been converted into a perhaps brackish estuary with quiet, shallow, sandy shores where *Cyclope* could be collected. Further rise of the sea destroyed this environment.

**Fig. 2** Stratigraphy of late Palaeolithic through early Neolithic marine shell assemblages from a trench (F/AS) in Franchthi Cave. Sampled units are shown vertical to no scale. Left, percentages of most important species; centre, total number of specimens in each sampled unit; right, shell zones and radiocarbon dates (yr BP).

Figure 1 shows a series of past shorelines using the shelf bathymetry and sea-level positions determined from a post-glacial sea-level rise curve. The present best value for the maximum lowering is 90–95 m and the shape of the following rise curve is still uncertain<sup>7–10</sup> and complicated by isostatic responses to ice removal and water addition<sup>11,12</sup>. Comparison of various proposed curves shows vertical uncertainties of 5–15 m for each of the chosen intervals which, for the shelf topography in our area, translate into horizontal uncertainties of a few hundred metres. For our purpose the shorelines so determined are adequate. Little modern sediment is present on the shelf<sup>6</sup> and the present water depths are a sufficient guide. In Koiládha Bay, where sediments are thicker, we have used coastal outlines from a more detailed study<sup>6</sup>.

It has been argued that the Holocene sea-level rise around the Peloponnese was accompanied by vertical crustal movements<sup>13–16</sup>, including a subsidence of 1–2 m kyr<sup>-1</sup> for the southern Argolid. If true this would shift all shoreline positions seaward by 0.51 km. The evidence for the southern Argolid is weak<sup>13–17</sup>, but if true it lengthens the walking distance to the sea before 8,000 yr BP by at least 1 km.

Three aspects of the reconstructed early Holocene shores are of interest; the rocky or sandy/muddy nature, the distance to the cave, and the presence of sheltered shoals or brackish lagoons or estuaries. The present coast is mainly rocky with offshore rocky flats and occasional pocket beaches. Large sand or gravel beaches exist only in Koiládha Bay and the bay north of Franchthi. During the early Holocene the situation was quite different. The smooth offshore topography with a slope of less than 0.6° implies an alluvial coastal plain, confirmed by seismic reflection data<sup>6</sup>. Only along the extreme north and south coasts a rough bottom suggests a possible rocky shore before 8,000 yr BP. Thus only 30–45% of the coast was rocky as contrasted to >75% today.

During the late Palaeolithic and much of the Mesolithic the coast was from 3.5 to 6.5 km away depending on whether one assumes subsidence. It is thus not surprising that whatever the shore may have yielded in seafood did not find its way into the cave deposits in quantity. The gradual approach of the sea to 4 km is, however, reflected in the appearance of some shells around 11,000 yr BP.

Shortly before 9,000 yr BP shells increase in number (Fig. 2). At this time the simple, straight shoreline had begun to develop embayments and capes ~2 km away, but remained sedimentary. Of the several streams the largest, the Koiládha river, was much larger than its modern successor<sup>6</sup> and flowed semi-permanently until ~7,000 yr BP. On the open coastal plain its valley was wide and had little effect on the shoreline, but as the sea approached Franchthi a bay was formed around 9,000 yr BP in the here much steeper and narrower valley. By 8,000 yr BP a narrow estuary existed just west of the present cave entrance which may have been closed by a bar at the outer shore; a sediment ridge occurs at the appropriate spot and depth (25 m) on seismic profiles<sup>6</sup>. Given the larger and more permanent river flow and the presence of copious freshwater springs at the foot of the Franchthi cliffs<sup>18</sup> it is possible that the estuary was brackish or had a variable salinity rather than the high salinity typical for lagoons in the Argolid today. Such an estuary, with sheltered and shallow shores, would provide an ideal habitat for *Cyclope* within a few hundred metres of the cave.

Thus the environments postulated earlier are probable at the right time and in the right place to explain extensive utilization of *Cyclope* on an open shore or in a sheltered and perhaps brackish bay<sup>19</sup>. Later, between 8,000 and 7,000 yr BP, further advance of the sea eliminated the bar<sup>9</sup> and opened the estuary. Simultaneously, however, the limestone cliffs north of Franchthi became part of the littoral zone and their rocky shores provided a good habitat for *Cerithium* within a few kilometres from the cave.

Bones of large tunny appear at the base of the *Cyclope* zone, a species hitherto not used<sup>18</sup>. N. J. Shackleton (personal communication) has postulated an increase in biological productivity

in the Aegean at this time which might explain this use of a new species. We also suggest that the development of an embayed coast around 9,000 yr BP may have facilitated the capture from shore of this open sea fish. The same productivity increase would also have enlarged the shellfish available.

During the next few years much evidence from Franchthi will become available to test and amplify ideas such as those we have presented. We hope that this paper will stimulate the integration of archaeological and environmental information.

In the summer of 1980, we found abundant live *Cyclope neritea* near the beach at the head of the Gulf of Argos between Nauplion and Nea Kios, and also in small numbers in the Bay of Astakos in Acharnania. In both cases *Cyclope* lived at the surface of fine silty-muddy sand in very shallow depths of 5–15 cm, on quiet and extensive shallow flats off the beach, an environment that corresponded exactly to the first of the two postulated here.

## Radiometric dating of sediments using fission tracks in conodonts

H. M. Sachs\*, M. Denkinger\*, C. L. Bennett† & A. G. Harris‡

\* Geological and Geophysical Sciences and †Physics Departments, Princeton University, Princeton, New Jersey 08544

‡ US Geological Survey, US National Museum, Washington, DC 20560

Conodonts are microfossils which are commonly found in marine rocks of Cambrian to Triassic age. Although their biological affinities are difficult to assess, conodonts are valuable stratigraphical indices for much of their geological range<sup>1</sup>. Recent work has also established that conodont colour alteration indices (CAI) are useful guides to diagenetic temperatures and hence burial depth<sup>2</sup>. Fission tracks<sup>3</sup> in conodonts allow measurement of uranium concentrations and estimates of 'age' to be made using isotopic methods<sup>4</sup>. We report here that fission tracks counted in irradiated, thermally unaltered (as indicated by CAI) middle Palaeozoic conodonts indicate typical uranium concentrations of ~1 part in 10<sup>9</sup>, with some samples higher. A single specimen of *Siphonodella* from the Lower Mississippian yielded an age estimate of 380 ± 140 Myr consistent with conventional interpolations. This method may also allow the unroofing of deeply buried sediments to be dated.

Table 1 Summary of data

| Sample code | Mineral | Spontaneous            |         | Induced                 |         | Fluence ( $\Phi t$ ) neutrons $\text{cm}^{-2}$ | $T$ (Myr) | $\pm 1\sigma$ (Myr) | No. of grains or fields | p.p.b. |

\* Slide contains two conodonts.

† No. of tracks actually counted to determine the reported track density.

Conodonts consist of carbonate apatite and trace amounts of organic material<sup>5</sup> and their structure consists of concentric lamellae, usually around a single growth centre. Lamellae of many conodonts average 2–3  $\mu\text{m}$  thickness, with some interlamellar spaces of 0.5–1.0  $\mu\text{m}$  thickness<sup>6</sup>. Individual crystallites are generally smaller than 0.01  $\mu\text{m}$  and optically unresolvable (R. Phillips, cited in ref. 7). The crystallites are predominantly co-parallel, with optic  $c$ -axes parallel to the direction of growth (perpendicular to lamellae) in most cases<sup>8,9</sup>.

The heavy nuclear particles released from spontaneous fission of  $^{238}\text{U}$  leave narrow damage tracks in most dielectric solids, generally 8–20  $\mu\text{m}$  long (track lengths vary among mineral species). In crystals, the trajectory is marked by vacant lattice sites and/or interstitial atoms. These features are permanent unless the solid is heated to its annealing temperature, at which point the tracks begin to disappear<sup>3</sup>. In general, fission tracks are exposed by chemically etching random polished surfaces of solids, and examining the specimen optically at high magnification. Etch kinetic arguments, based on the expectation of high dissolution rates along crystallite boundaries, have discouraged earlier efforts to find fission tracks in conodonts.

Assuming reasonable etch efficiency, the feasibility of fission track work depends on the weight concentration of uranium ( $c$ ) and the age ( $A$ ) of the sample. Fleisher and Price<sup>3</sup> suggested a minimum track density of 100  $\text{cm}^{-2}$  for routine searches, corresponding to  $cA \geq 0.3$ . This requires  $\sim 2$  h in favourable conditions. For middle Palaeozoic conodonts (300 Myr), this corresponds to  $[U] \geq 1$  part in  $10^9$ . Because conodonts are small ( $\sim 1$  mm),  $cA = 0.3$  will substantially underestimate the time required to count many grains instead of a single homogeneous surface.

For dating, only the relative densities of spontaneous and induced tracks in the same specimen are needed. In contrast, using fission tracks to measure uranium concentration requires determining the specimen size, the number of spontaneous (fossil) tracks (or, alternatively, annealing the sample to remove pre-existing tracks), and counting the tracks from fission events caused by irradiation with a known dose of thermal neutrons. In this context, the first step is to establish methods which allow the tracks to be seen and which allow the conodonts to be handled for irradiation.

Surface preparation requires mounting and fine polishing. Each set of conodonts was randomly mounted in epoxy wafers and one surface ground until all specimens were exposed. The mount was then reversed, ground face to glass, and cemented to standard petrographical slides. Samples were ground to  $\sim 0.05$  mm and the surface finally polished with 0.25  $\mu\text{m}$  diamond grit—the minimum surface roughness acceptable for high magnification optical searches. Parallel-ground specimen surfaces seem crucial for reliable optical examination. After many trials, we chose as standard etch 0.25% nitric acid for 60 s (ref. 4).

Following a thorough search (using transmitted light differential interference contrast microscopy at  $\times 1,250$ ) to determine the number of spontaneous tracks, the wafer was cleaned and removed from the glass slide for irradiation (both glass and Lexan became unacceptably radioactive when irradiated).

Each sample was wrapped in aluminium foil, as was the NBS calibration glass<sup>10</sup>, when used.

A thermal neutron dose of  $2.0 \times 10^{16}$  neutrons  $\text{cm}^{-2}$  yielded usable results (Brookhaven National Laboratory, HFBR facility, V-II Port, D. Rohrer, personal communication). Epoxy-embedded, foil-wrapped samples were 'cool' enough for shipment almost immediately, and handling required only modest precautions. No special facilities were required.

Irradiated wafers were remounted on petrographical slides (for ease of handling), reground and etched again for optical examination and track counting. Grinding to a new surface maintained a 'solid' counting geometry—the expectation of finding track fragments from the solid volume instead of a half-space.

We obtained the following results: (1) Middle Ordovician simple conodonts and conodonts with 'white-matter'<sup>11</sup> which we tested darkened and become opaque during irradiation; we were unable to count tracks. (2) Although the track densities were very low, the distribution of induced tracks in platform conodonts appeared uniform, with no apparent concentration near edges, interlamellar spaces or other obvious features. We inferred that the uranium was disseminated in the apatite structure. Altschuler *et al.*<sup>11</sup> have suggested that uranium in conodonts would replace calcium. This is reasonable because the ionic radii of divalent Ca (0.99 Å) and tetravalent U (0.97 Å) are so similar<sup>12</sup>. (3) Our best results were obtained with platform conodonts which showed no visible colour alteration (CAI = 1). Induced track densities of  $2.0$ – $2.6 \times 10^3$  tracks  $\text{cm}^{-2}$  and  $2.4$ – $8.1 \times 10^4$  tracks  $\text{cm}^{-2}$  for  $3 \times 10^{15}$  and  $1.6 \times 10^{17}$  thermal neutrons  $\text{cm}^{-2}$ , respectively, yielded concentrations of 1.9–2.4 and 0.4–1.4 parts per  $10^9$  (p.p.b.) (Table 1), comparable with estimates by Naeser (personal communication). In eight nonirradiated specimens searched for fossil tracks, we found no tracks in five specimens, one each in two, and two tracks in one specimen. These track densities are expected for Palaeozoic samples with  $\sim 1$  p.p.b. [U]. (4) Two specimens tested 'blind' (CDR-2 and CDR-4) yielded 12 and 10 well defined fossil tracks respectively, indicating order-of-magnitude higher [U] than other samples studied. CDR-2 was ground off inadvertently while repolishing after irradiation, but CDR-4 yielded 35 tracks from which we compute an age of  $380 \pm 140$  Myr, from  $A = 6.45 \ln [1 + 0.76 \Phi t (N_s/N_i)]$ , where age is  $10^9$  yr,  $\Phi t$  is the thermal neutron dose in  $10^{17}$  neutrons  $\text{cm}^{-2}$  and  $N_s(N_i)$  is the density of spontaneous (induced) fission tracks in the solid. In addition to the 10 (spontaneous) and 35 (induced) unambiguous tracks (see ref. 3), there were respectively 6 and 12 'track-like' markings rejected during counting by M.D. In addition to the criteria of ref. 3, we compared the observed distribution of track lengths and orientations with that expected for randomly oriented tracks. The two specimens counted were large platform conodonts of the genus *Siphonodella* from the lower Chappel Limestone, Llano region, Texas, locality C-25 of ref. 13. The age of this interval is given as 340 Myr (ref. 14).

Thus, it is possible to count fission tracks in conodonts and to compute reasonable age estimates from these data. Many improvements in procedures could be made. Our preparation routines work well but are tedious: for example, methods which

allow irradiation of specimens with their mounts would save time and eliminate the risks inherent in handling unsupported epoxy wafers. Fossil track counting statistics would be greatly improved by examining more than one surface on each specimen: multiple grind-etch-count cycles will greatly increase the number of tracks per conodont without affecting the induced track densities. We have limited information on the distribution of uranium concentrations in conodonts, but over 90% of the conodonts we have tested have had very low [U] (~1 p.p.b.). The precision of age estimates improves with the square root of the number of tracks counted. A reasonable target would be 100 spontaneous (fossil) tracks/age determination, which implies 10–100 conodonts examined for each accurate age determination.

Fission track dating of conodonts at stratotype boundaries and elsewhere may challenge conventional indirect age estimates based on correlation and interpolation from igneous rocks<sup>15</sup>. However, the scarcity of fission tracks in our conodonts suggests that much effort will be required to rival the precision of good radiometric determinations published for igneous rocks.

Nonetheless, the general dichotomy between (isotopically) datable but fossil-free igneous rocks and fossiliferous sedimentary rocks (which are the basis of the relative geological time scale) has complicated stratigraphical codes<sup>16</sup>. Except for <sup>14</sup>C dating of uppermost Pleistocene fossils, direct dating of fossils has been virtually impossible, but by eliminating the need to correlate datable rocks with those whose position in the stratigraphic column is secure errors may be reduced. The benefits of directly dating mid-Palaeozoic rocks justify studying fission tracks in conodonts.

The greatest value of dating conodonts directly probably lies in studying the thermal history of sedimentary basins<sup>17</sup>. Because the annealing temperature of apatite is ~90–100 °C, corresponding to burial of 3–5 km (ref. 18), the fission track 'clock' only begins to run as deeply buried sediments are uplifted and unroofed. If we can count tracks in thermally altered conodonts, we can date the time at which the overburden thinned (structurally or by erosion) to 3–5 km. (If one tests conodonts from various burial depths in the same section, the fission track 'ages' (unroofing times) will decrease with increasing depth (depositional age) in the rock column, as seen in igneous and metamorphic rocks in an Alaskan drill hole<sup>19</sup>.)

This work was begun with a question by S. T. Crough. We thank Z. S. Altschuler and A. G. Fischer for reviewing the manuscript, C. W. Naeser for advice and assistance, and R. Milwicz for monitoring radiation safety protocols. This work was supported by Princeton University Department of Geological and Geophysical Sciences and in part by NSF grant PHY 78-01473.

## First pterosaur from Australia

R. E. Molnar

Queensland Museum, Gregory Terrace, Fortitude Valley, Queensland 4006, Australia

R. A. Thulborn

Department of Zoology, University of Queensland, St Lucia, Queensland 4067, Australia

**We report here the first evidence of pterosaurs from Australia. Our report is based on fragmentary material from marine Lower Cretaceous sediments, of the Eromanga Basin, western Queensland. These fragments represent at least one pterosaur allied to the well-known *Pteranodon*<sup>1,2</sup>, and establish a new southern limit of distribution for Cretaceous flying reptiles.**

The material (Fig. 1) comprises three uncrushed specimens—the front of the fused mandibles (QM F10613), a single vertebra (QM F10614) and an isolated left scapulocoracoid (QM F10612). These were collected from flaggy limestones of the Toolebuc Formation at an unnamed locality 13 km south of Hamilton Hotel and about 70 km east of Boulia, west Queensland. The skull fragment and vertebra came from a single slab, and the scapulocoracoid was found about 500 m away. The Toolebuc Formation consists of crystalline and, in places, concretionary limestones with minor bands of shale; it has been dated as Lower Cretaceous (Albian)<sup>3,4</sup> on the basis of its rich and varied marine fauna (including lamellibranchs, gastropods, belemnites, ammonites, fishes and marine reptiles).

The skull fragment (Fig. 1a, b) comprises the slender extremities of both mandibles, showing several characteristic pterosaur features: (1) the long fused symphysis; (2) the interior

**Fig. 1** a, Anterior region of mandibles of pteranodontid (Queensland Museum (QM) F10613) from Toolebuc Formation of Queensland, in palatal view. Note replacement crown in fourth left alveolus. Scale bar, 2 cm. b, The same in lateral view. c, Vertebra of pterosaur (QM F10614) from the same locality, in anterior view. Scale bar, 1 cm. d, The same in posterior view; note large aperture into hollow transverse process. e, Pteranodontid scapulocoracoid (QM F10612) in anterior view. Scale bar, 2 cm. f, The same in posterior view.

**Fig. 2** Distribution of Cretaceous pterosaurs. Lower Cretaceous occurrences (left): 1, Oregon, *Pteranodon*?; 2, east Texas, unidentified; 3, Kansas, *Apatomerus*; 4, San Luis, *Pterodaustro* and *Puntanipiterus*; 5, Ceara, *Araripidactylus* and *Araripesaurus*; 6, southern England, *Criorhynchus*, *Ornithocheirus* and *Ornithodesmus*; 7, France, *Ornithocheirus*; 8, Germany, 'Ornithocheirus'; 9, Jordan, *Titanopteryx*; 10, Rajasthan, unidentified; 11, Dzungaria, *Dsungaripterus* and *Noriopterus*; 12, Shandong, unidentified; 13, Queensland, aff. *Ornithocheirus*. Upper Cretaceous occurrences (right): 14, Alberta, 15, Arizona, 16, Wyoming, 17, Montana, 18, South Dakota and 19, Alabama, unidentified; 20, west Texas, *Quetzalcoatlus*; 21, east Texas and 22, Delaware, *Pteranodon*; 23, Kansas, *Nyctosaurus* and *Pteranodon*; 24, Paraíba, *Nyctosaurus*; 25, southern England, *Criorhynchus*, *Ornithocheirus* and *Ornithostoma*; 26, Austria-Bohemia, 'Ornithocheirus'; 27, Transylvania, unidentified; 28, Zaire, cf. *Ornithocheirus*; 29, Petrovsk, *Ornithostoma*; 30, Hokkaido, *Pteranodon*.

of the jaws, exposed through breaks, was coarsely cancellous, or perhaps hollow; (3) the flat lateral surface of each ramus slopes down and inwards, giving a triangular cross-section (slightly deeper than wide); (4) the oral surface is transversely convex with a narrow median groove marking the line of the symphysis; (5) a distinctive arrangement of the teeth.

On each side are five deep and widely spaced alveoli, whose thin outer walls form distinct bulges in the jaw margins. Each alveolus is elliptical (with long axis longitudinal), and opens upwards and slightly laterally. The first alveolus on each side evidently carried a near-procumbent tooth; the second is more steeply inclined, whereas the following alveoli are almost vertical. Structure and size of the alveoli indicate a thecodont, near-isodont dentition at the front of the lower jaw. The fourth left alveolus contains a damaged replacement tooth; its crown is latero-medially compressed, and seems to have been tall and sharply pointed. In all respects the specimen is very similar to jaw fragments attributed to *Ornithocheirus*<sup>5,6</sup> from the Cambridge Greensand (Cenomanian<sup>7,8</sup>) of England.

The single vertebra (Fig. 1c, d) is incomplete, but shows most of the neural arch and the anterior part of the centrum. The centrum is relatively small and has a deeply concave anterior face, kidney-shaped in outline (concave above) and much broader than high. The walls and processes of the arch are virtually hollow, containing large cavities traversed by fine struts of bone. This system of cavities opens to the exterior in three places (seen on the well-preserved right side of the specimen): through a large triangular opening in the rear surface of the stout transverse process, and through smaller openings beneath the transverse process and below the base of the prezygapophysis. The robust neural spine is almost square in profile; its anterior margin is thick and flat, whereas its rear margin is narrower and carries a shallow vertical groove. The stout prezygapophyses have large articular facets inclined at about 30° from vertical; the postzygapophyses are smaller and sharper, each supported by a low ridge extending up and back from the base of the transverse process.

This pneumatic vertebra, with its depressed and probably procoelous centrum, is clearly from the presacral region of a pterosaur<sup>6,9</sup>. The postzygapophysial facets are much smaller than the prezygapophysial, which may indicate that the vertebra was transitional between the flexible cervical series and the rigid notarium<sup>6,9</sup>. The grooved rear margin of the neural spine suggests an articulation with the front of the notarium. Detailed comparisons are difficult because the vertebrae of other pterosaurs are usually crushed flat. Presacral vertebrae of *Pteranodon*

have similar oblique ridges supporting the postzygapophyses, but have relatively thin neural spines and seem to lack pneumatic openings<sup>1</sup>. The rather thick neural spine is matched in *Ornithodesmus latidens*<sup>10</sup>, from the Wealden of England, and in the notarium of *Dsungaripterus weii*<sup>11</sup>, from the Lower Cretaceous of China.

The scapulocoracoid (Fig. 1e, f) lacks only its uppermost tip and parts of the antero-medial margin. In postero-lateral view the specimen is roughly V-shaped (open posteriorly), with scapular and coracoidal wings enclosing an angle of about 75°. It shows a combination of features unknown in vertebrates other than pterosaurs<sup>6,9,12</sup>: (1) A cancellous interior overlain by a smooth cortex less than 1-mm thick, revealed at the damaged areas. (2) Scapula and coracoid are basically rod shaped with oval cross-sections, expanding considerably where they meet to form the glenoid; the intervening suture has been obliterated by fusion, but probably ran horizontally through the central and deepest part of the glenoid. (3) On the medial side the glenoid region is strengthened by a vertical buttress enclosing a narrow slit-like fenestra. (4) The large glenoid opens laterally, and slightly to the front, with margins developed into thick 'lips' of bone. It is essentially an open groove, aligned antero-posteriorly, with flattened upper and lower walls meeting at slightly more than a right angle. In outline it resembles three-quarters of a square: its upper (scapular) wall is about twice as long as its lower (coracoidal) wall, and forms a distinct overhang posteriorly. (5) The scapula is nearly straight, and extends medially as well as up and backwards from the glenoid; this oblique, and partly transverse, orientation suggests that the scapula may have articulated with a notarium<sup>9,12,13</sup>.

Just above the postero-dorsal corner of the glenoid the rear margin bears a prominent triceps tubercle<sup>12</sup>. The coracoid is slightly curved (convex downwards), and about halfway along its dorsal surface bears a low longitudinal crest probably marking the coracobrachialis attachment<sup>2</sup>. The tip of the coracoid is damaged, but enough remains to show a rounded surface for articulation with the sternum.

In general appearance the specimen is very similar to scapulocoracoids of the Upper Cretaceous pterosaurs *Nyctosaurus*<sup>14</sup> and *Pteranodon*<sup>1</sup>, the most obvious difference being the less strongly developed triceps tubercle in these latter forms. The specimen seems to be virtually identical to an incomplete scapulocoracoid attributed to *Ornithocheirus sedgwickii*<sup>5,6</sup>, from the Cambridge Greensand of England.

Evidently, the Toolebuc material represents one or more pterosaurs of the suborder Pterodactyloidea. The specimens are

most closely matched in pterodactyloids such as *Ornithocheirus* and *Pteranodon*, and the medial buttress of the scapulocoracoid occurs only in certain pterodactyloids<sup>12</sup>. In addition, there is indirect evidence of a notarium, a structure unknown outside the Pterodactyloidea. It is difficult to assign the Toolebuc material to a family because the two most similar forms, *Ornithocheirus* and *Pteranodon*, are at present in different families<sup>12</sup>. The Toolebuc scapulocoracoid is nearly identical to that attributed to *O. sedgwickii*<sup>6,9</sup>, but this species is known only from dissociated fragments and the referred scapulocoracoid might belong to another Cambridge Greensand pterosaur, *Ornithostoma seeleyi*<sup>15</sup>. *Ornithostoma* may, in turn, be identical with *Pteranodon*<sup>2,6,15</sup>. The jaw fragment is clearly from a pterosaur unlike the toothless *Pteranodon*, and is most closely matched in *Ornithocheirus*. Adherence to the pterosaur classification given by Wellnhofer<sup>12</sup> would require assignment of the Toolebuc jaw fragment to one family (Ornithocheiridae) and of the scapulocoracoid to another (Pteranodontidae). Distinctions between Ornithocheiridae and Pteranodontidae are, perhaps, of doubtful validity, largely because material attributed in the past to *Ornithocheirus* is fragmentary and of uncertain status. The problem is exacerbated by a possibility that the Toolebuc material represents more than one animal. In view of these difficulties, we recommend that the Toolebuc material be provisionally assigned to the family Pteranodontidae *sensu lato* (including Ornithocheiridae *sensu stricto*), following the usage of Romer<sup>6,16</sup>. The Toolebuc pterosaur material may be identified as aff. *Ornithocheirus*.

The best-known members of the Pteranodontidae *s.l.*, *Nyctosaurus* and *Pteranodon*, are of Upper Cretaceous age, whereas the earliest representatives come from about the boundary between Lower and Upper Cretaceous: from the Cambridge Greensand (Cenomanian<sup>7,8</sup>) of England<sup>6,12,15</sup> and the Hudspeeth Formation (Albian, possibly Cenomanian<sup>17</sup>) of Oregon<sup>12</sup>. The Toolebuc pterosaur is certainly Albian in age<sup>5,4</sup> and, hence, one of the earliest pteranodontids yet discovered.

*Pteranodon* and its allies were probably soaring maritime creatures<sup>2</sup>, similar in their habits to oceanic birds of today, and it is not surprising that they should have been widely distributed. Even so, few pteranodontids have been discovered in the Southern Hemisphere (Fig. 2), and the material described here establishes a new southern limit for their occurrence (indeed, for the occurrence of any Cretaceous pterosaur).

In *Pteranodon*, which attained a wing-span of about 7 m, the maximum dorso-ventral height of the scapulocoracoid is equivalent to some 5% of the total wing-span (calculated from data in ref. 2). The Toolebuc scapulocoracoid is only slightly damaged and probably had a maximum height of about 10.7 cm when complete. We estimate, by comparison with *Pteranodon*, that this scapulocoracoid was derived from a pterosaur with a wing span of about 2 m.

We thank Mr S. Van Dyck for his assistance in the field, and also Drs J. H. Ostrom and P. Wellnhofer. This work was supported by a grant from the Australian Research Grants Committee.

The primate visual cortex, including that of man, receives separate input from each eye and these interact in binocular cortical neurones. This organization is known to be vulnerable to disruption in early life<sup>1</sup>. To understand the development of human visual cortex, and to detect and assess disorders of binocular function at the earliest possible age, a robust method is needed for detecting binocular interactions in the infant's visual system. We have done this by recording cortical visual evoked responses (VERs) to the onset and offset of binocular correlation in a large-screen dynamic random dot display. We report here that, in general, the human infant has a functional binocular visual cortex by 3 months of age, with some individuals showing cortical binocularity at an earlier age.

We used a stimulus display which has been found to yield prominent VERs in adult subjects with normal binocular vision<sup>2,3</sup> and in an alert macaque monkey<sup>4</sup>, and which does not produce VERs in patients whose binocular function has been impaired by monocular retrobulbar neuritis<sup>5</sup>. It consists of a random dot pattern generated on red and green channels of a projection video monitor (Advent 1000 A), producing a large-screen back-projected display (157 × 130 cm), with each dot 8 × 5 mm; at the infant's viewing distance of 40 cm this gave dots 1.1 × 0.7 degrees in a display 126 × 117 degrees. The stimulus alternates between a correlated phase, in which the dot patterns are identical in the red and green channels, and an anti-correlated phase in which a dark dot in the green channel corresponds to every bright dot in the red and vice versa. Because a fresh random dot pattern is generated for each TV frame (that is, at 30 Hz), the alternation between these phases is not detectable in either channel viewed alone. When the channels are displayed to the two eyes separately, by means of red and green Wratten filters over the projection lenses and corresponding filters in lightweight goggles worn by the infant, the stimulus alternation can only be detected by binocular interaction, that is, it is 'strongly cyclopean' (ref. 6). The use of correlation/anti-correlation has the merit for infant testing that the binocular relationship is not affected by head tilt. At slow rates of alternation, the correlated phase appears to an adult as dynamic noise on a well-defined flat surface, whereas the anti-correlated phase appears rivalrous and incoherent in depth. In preliminary experiments we found that an alternation rate of 1.9 Hz was optimal for VER recording. At this rate it was difficult to differentiate the two alternating percepts, but a clear pulsation of the display at the alternation frequency was visible with binocular viewing.

Bipolar VERs were recorded from a pair of Grass gold electrodes 1 cm above the inion and at the vertex, with an indifferent electrode on the forehead. Interelectrode resistances between 5 and 20 kΩ were generally attained. Potentials were amplified with a passband of 0.25–15 Hz and cumulated in a signal averager with a 1.024 s sweep, each sweep containing two

\*Present address: Department of Experimental Psychology, University of Cambridge, Downing St, Cambridge CB2 3EB, UK.

**Table 1** Proportion of infants showing significant VERs with cyclopean stimulus, compared with control conditions

| Age range*       | No. of infants in group | Number of infants showing cyclopean VER |
|------------------|-------------------------|---|
| 4 weeks–2 months | 9                       | 4                                       |
| 3–5 months       | 9                       | 9                                       |
| 5–8 months       | 8                       | 6                                       |

\* There were no infants in the age range 10–13 weeks inclusive in the sample.

cycles of the stimulus alternation. The averager automatically rejected sweeps containing high-amplitude artefacts, and averaging was manually interrupted when the infant was drowsy, agitated, making gross movements, or looking away from the display. (The success of the experimenter holding the infant in minimizing these states is critical to the success of the procedure.) The cumulated evoked response was plotted after 25, 50, 75, and 100 sweeps, and the waveforms were digitized for analysis.

Subjects were healthy infants attending the paediatric clinic at Mount Sinai Hospital, and relatives of ophthalmological patients, and ages ranged between 4 and 36 weeks. They were tested when calm and alert, as far as possible, although it was more difficult to sustain this state through preparation and testing in the younger infants, especially following a long clinic attendance.

Five stimulus conditions were used for VER recording: (1) 'Contrast': when viewed without goggles, the display appears to alternate between a yellow-black (correlated) and a red-green (anti-correlated) dot pattern. This served to check that we could record VERs from a particular subject. (2) 'Red-green': viewed with goggles so that any VER recorded was due to activation of binocular cortical neurones. (3) 'Red-red' control: with goggles so that each eye saw the same channel. Any VER recorded here must be due to crosstalk between the channels, visibility of contrast changes round the edge of the goggles, or electrical artefact. (4) 'Misaligned control': correlation and anti-correlation were both destroyed by misaligning the patterns vertically by 10 degrees; again any VER is an indicator of crosstalk or artefact. (5) 'Looking away control' in which the infant was directed away from the display—this served principally as a control for the contrast condition. It was not possible to run all conditions on all infants, but in all the 27 infants whose data are reported, recordings were obtained in contrast, red-green, and one or more of the control conditions. In only five cases was it necessary to compare the red-green with the weakest, 'looking-away' control.

Figure 1 shows VERs recorded successively from a 2-month infant. In (a) a VER waveform at twice the frequency of the correlated/anti-correlated alternation clearly emerges in the course of 100 sweeps, (b) the patterns displayed to the two eyes are misaligned vertically and the VER is completely absent. In (c) the patterns are realigned and the VER reappears, (d) a single channel is displayed to both eyes and the VER is again absent. This infant therefore showed VERs which can only be a cortical response to binocular correlation.

In many infants the VER records were not so noise-free as in Fig. 1 (although amplitudes were generally greater—of the order of 10  $\mu$ V). We therefore adopted a statistical procedure for confirming the presence of a VER that cumulated over sweeps in the 'red-green' condition and was absent in controls.<sup>7</sup> The amplitude of a constant VER signal increases linearly with the number of sweeps which are cumulated, whereas noise amplitude, present in both test and control runs, increases as the square root of the number of sweeps. For each run we obtained a record of the cumulated signal after 25, 50, 75 and 100 sweeps. Each of these records was digitized, and its products computed with sine and cosine functions at the stimulus alternation frequency and its second harmonic, to give the amplitude and

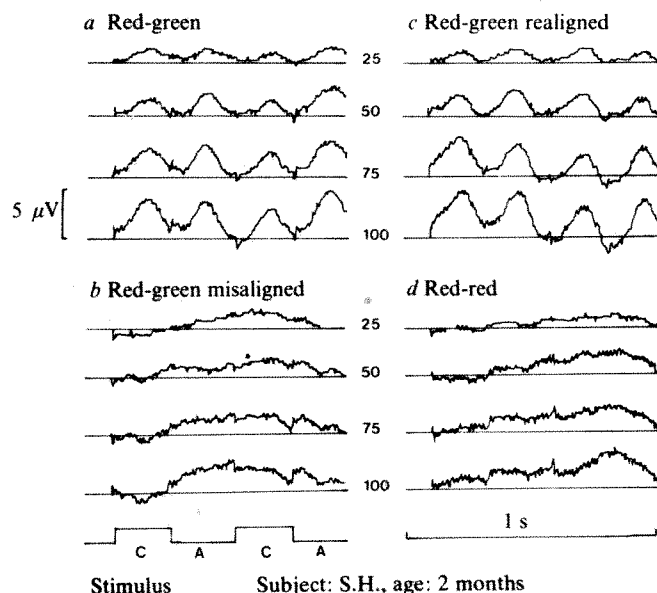

phase of components at these frequencies in the waveform. Regression lines were computed for the amplitude of each component as a function of number of sweeps for the records from a single run. It was taken as positive evidence for a binocular VER if the slope of the regression line for either component for a 'red-green' run was statistically significantly greater (at the  $P < 0.05$  level) than the slope for a control run.

The group of infants tested were divided by age into three groups. Table 1 shows the number of infants in each group from whom positive evidence of binocular VERs was obtained. All the infants who gave negative results showed satisfactory VERs in the contrast condition.

The VERs found could be either at the first or the second harmonic of the stimulus frequency. Generally, but not invariably, the VER obtained in the 'red-green' binocular condition was the same harmonic as that obtained with the same individual in the contrast condition.

In addition to the 27 infants included in Table 1, one 17-week infant with congenital esotropic strabismus was tested both before and the day after corrective surgery, and on both occasions this child showed a VER in the contrast condition but not in 'red-green' binocular viewing. It is too soon to know whether subsequent development of binocularity will be possible in this case, or whether the lack of binocularity was congenital and permanent.

We conclude that, at least by the age of 12 weeks, the normally developing human visual cortex contains neurones which are activated by binocularly correlated stimuli. Such neurones are clearly present in some younger infants. We do not know whether the failure to elicit VERs in half the infants under two months indicates a true absence of functional binocularity, or simply the more labile attentional state of these younger infants. It is possible, but in our view unlikely, that the apparent lack of binocularity in some younger infants could have been due to errors of convergence<sup>8</sup>. We believe that the failure to

**Fig. 1** Visual evoked responses (VERs) recorded from a 2-month infant using a 'cyclopean' stimulus: (a) the infant wore 'red-green' goggles so that the two eyes saw different pattern components. The stimulus trace (bottom left) shows the alternation between binocular correlation (C) and anti-correlation (A): a VER synchronized with the stimulus changes is clearly present; (b) when a vertical misalignment of the two eyes' patterns was introduced the VER disappeared; (c) the alignment of the patterns was restored and the VER reappeared; (d) when both eyes see the same pattern component (through 'red-red' goggles) no VER is present. The four traces for each condition represent the cumulated signal after 25, 50, 75 and 100 sweeps within a single run. Any true VER will appear with progressively increasing amplitude in such a series.

demonstrate binocular VERs in two infants of the oldest group can be ascribed to the very noisy signals obtained from these more active individuals.

Other behavioural investigations have tested whether infants can discriminate areas of stereoscopic disparity within a static or dynamic random dot stereogram<sup>9,10</sup>. The most extensive of these<sup>9</sup> found evidence for stereoscopic discriminations in 3½-month but not in younger infants. It is possible that an infant could have cortical neurones which responded to binocular correlation in our experiment, but which did not respond differentially to binocularly correlated patterns with varying disparities. Binocular cells without any fine degree of disparity tuning have been reported in the immature visual cortex of the cat<sup>11</sup>. Further behavioural and evoked potential studies, which compare the random dot correlograms used here with random dot stereograms, are required to test whether the binocularity found in at least some infants under 3 months is of this nature. In

adults, both dynamic random dot correlograms (the stimulus used in this study) and stereograms yield large VERs, but of different shapes<sup>2</sup>.

Animal<sup>1,12</sup> and human<sup>13</sup> studies have shown that binocular organization is vulnerable to environmental modification, implying that early correction of binocular disorders such as strabismus may be critical. Our demonstration of cortical binocularity in normal 3-month-old infants opens the possibility that this robust VER method could be used to diagnose and assess early abnormalities of binocular development and effects of treatment.

## Bloom-forming cyanobacterium *Microcystis aeruginosa* overwinters on sediment surface

T. Preston & W. D. P. Stewart

Department of Biological Sciences, University of Dundee, Dundee DD1 4HN, UK

C. S. Reynolds

Freshwater Biological Association, Ambleside, Cumbria LA22 0LP, UK

Cyanobacteria (blue-green algae) commonly occur in the phytoplankton of lakes and reservoirs and sometimes develop as blooms which can cause deoxygenation, toxin production and nuisance odours<sup>1</sup>. The factors which govern the occurrence and seasonal development of such blooms in surface waters are imprecisely understood and little is known about the origins of the bloom-forming populations within particular water bodies (see, however, refs 2, 3). Using <sup>15</sup>N as tracer, we show here that the appearance of *Microcystis* in the phytoplankton of an experimental enclosure in the summer of 1977 correlated directly with the presence of particulate <sup>15</sup>N which could only have been sediment-derived and which originated mainly from *Microcystis* cells deposited on the sediment surface the previous year. The most plausible explanation is that *Microcystis* overwinters on the sediment surface and by so doing provides an inoculum of colonies from which the epilimnetic population develops the following summer<sup>4–8</sup>. Possible mechanisms which allow the mass recruitment of *Microcystis* to the plankton are considered elsewhere<sup>2,3</sup>.

On 19 August 1976, 11 kg NaNO<sub>3</sub> (enriched with 9.63 atom% excess <sup>15</sup>N) and 789 g KH<sub>2</sub>PO<sub>4</sub> (N:P atomic ratio, 10:1) were dissolved and sprayed onto the surface waters of an 18,500 m<sup>3</sup> experimental enclosure (45.7 m diameter, 12 m deep)<sup>9</sup> in Blelham Tarn in the English Lake District when the waters were thermally stratified<sup>10</sup>.

When the fertilizer was added, algal biomass in the water column was low (<5 µg chlorophyll *a* per l) but within 14 days an extensive bloom dominated by the cyanobacterium *Microcystis aeruginosa* developed in the epilimnion. In October,

stratification broke down and the particulate <sup>15</sup>N in the water column (7.2 kg N enriched with 1.31 atom% excess <sup>15</sup>N) sedimented out (Fig. 1). Light microscopy showed the sedimenting material to be almost entirely (>90% by volume) *Microcystis* colonies. This was deposited on the sediment surface as a layer approximately 1.0 cm thick and clearly visible in sediment core samples. On 19 February 1977 the layer of *Microcystis* still dominated the sediment surface and the cells then had a <sup>15</sup>N enrichment of 1.33 atom% excess <sup>15</sup>N; only 7.5% (9 g <sup>15</sup>N) of

**Fig. 1** The distribution of particulate <sup>15</sup>N (total particulate N × atom% excess <sup>15</sup>N enrichment) in the water column and sediment of a Lund enclosure (enclosure A) in Blelham Tarn, English Lake District from July 1976 to February 1977. ■, >8; ▒, 5–8; □, 1–5; □, 0–1 (all µg per l). Water samples were collected using a 5 l Friedinger bottle; sediment core samples were obtained using a Jenkins surface sediment corer<sup>12</sup>, particulate material was separated by filtration onto precombusted Whatman GF-C disks; organic C and total N were measured using a Hewlett Packard 185B elemental analyser or by Kjeldahl digestion. Isotope analyses were carried out on Kjeldahl distillates after conversion of the NH<sub>4</sub><sup>+</sup> to N<sub>2</sub> using LiOBr (ref. 13). Isotope ratios were determined using a VG Micromass MM601 mass spectrometer.

the total isotope present in the sediment had been mineralized. The experiment therefore provided a labelled sediment population whose subsequent fate could be followed.

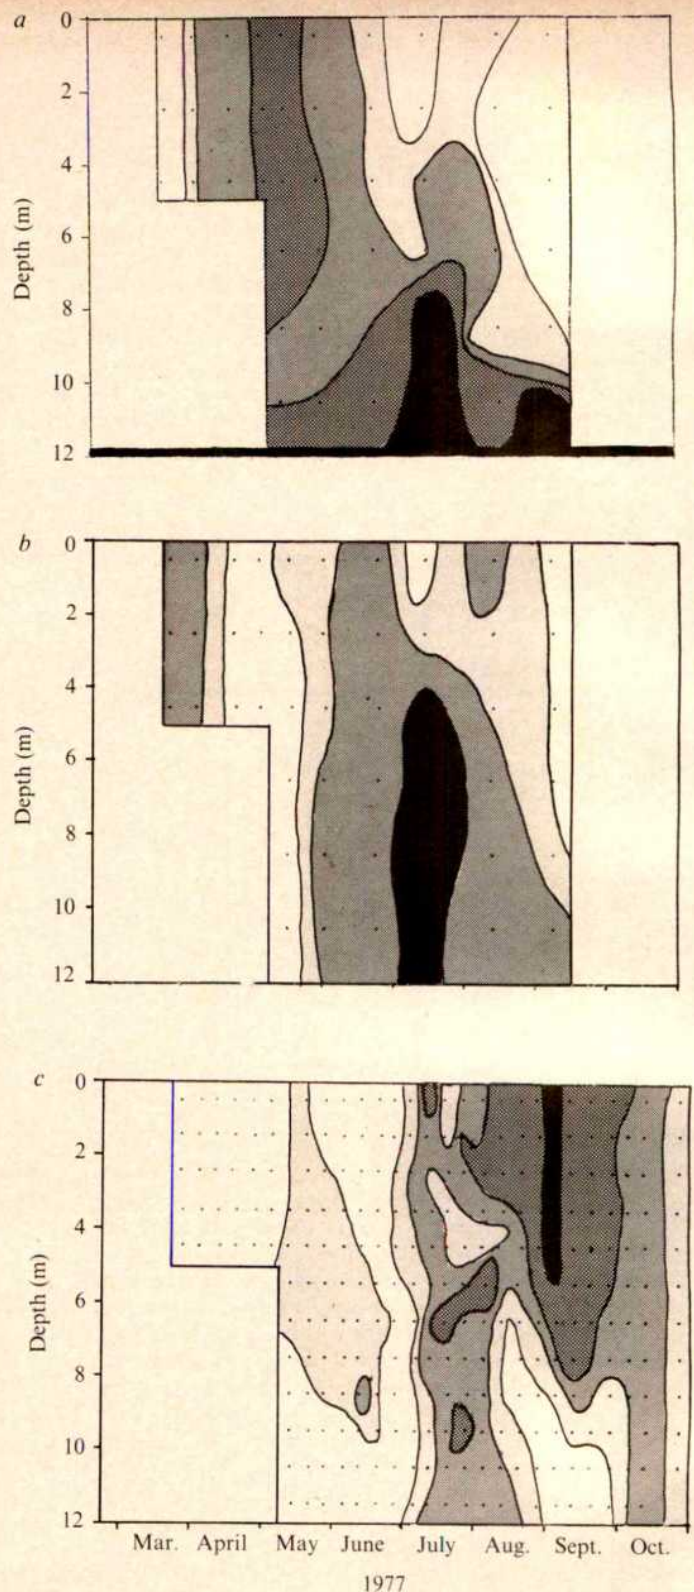

The walls of the enclosure were lowered on 20 February 1977 to equilibrate the isothermal waters with those of the Tarn and thus remove  $^{15}\text{N}$  from the water column. After 30 days the walls were raised and the  $^{15}\text{N}$  content of the particulate and soluble material in the water column was subsequently monitored.

Figure 2a presents data on the particulate  $^{15}\text{N}$  found in the water column from the time of isolation of the enclosure (22 March 1977) until late September 1977. It is seen that very little particulate  $^{15}\text{N}$  was present in the water column immediately after isolation (10–100-fold lower than that present before opening the enclosure; see Figs 1 and 2a), indicative of the success of the flushing procedure. Particulate  $^{15}\text{N}$  concentrations in the surface waters then increased to a maximum in May. As soluble  $^{15}\text{N}$  was undetectable in the water column until August when  $^{15}\text{NH}_4^+$  was first released from the sediment into the anoxic hypolimnion, the particulate  $^{15}\text{N}$  increase must have been sediment-derived. This particulate  $^{15}\text{N}$  increase in May corresponded with the first appearance of *M. aeruginosa* in the water column (see Fig. 2c). An epilimnetic decline in particulate  $^{15}\text{N}$  then occurred with the onset of stratification in June.

In mid-July a very pronounced input of  $^{15}\text{N}$  was noted below 7.5 m. Over the period 21 June–12 July this input was 230 mg  $^{15}\text{N}$  and the net increase in the whole enclosure was 84 mg  $^{15}\text{N}$ . That is, there was significant movement of sediment-derived  $^{15}\text{N}$  particulate material into the hypolimnion. The integrated water column  $^{15}\text{N}$  concentration in mid-July was 940 mg  $^{15}\text{N}$  (1% of that present on the sediment surface). On analysing the subsequent changes in particulate  $^{15}\text{N}$  over the period 12 July–11 August, a net decrease in particulate  $^{15}\text{N}$  occurred, due presumably to some material sedimenting. However, of more importance, there was an input of 122 mg  $^{15}\text{N}$  to the epilimnion. That is, the particulate  $^{15}\text{N}$  which originated in quantity from the sediment in mid-July had reached the surface waters. In late September the particulate  $^{15}\text{N}$  sedimented.

Figure 2b, c provides information on the nature of the particulate material in the water column. The carbon-to-nitrogen (C:N) ratio data (Fig. 2b) show that immediately after isolating the enclosure in March the particulate material had a C:N ratio of 10.4:1. This ratio then increased to a maximum of 12.2:1 in early May indicating that the particulate material had a large detrital component. A particulate  $^{15}\text{N}$  maximum also occurred then (see Fig. 2a). In mid-July the C:N ratio changed sharply at depth to <9 indicative of the presence of phytoplankton (the C:N ratios of healthy *Microcystis* the previous year were 7–8:1) with minimum C:N values (8:1) being found where the particulate  $^{15}\text{N}$  concentration was also highest (8.5 m; see Fig. 2a). In August the C:N ratios in the surface waters decreased to a minimum.

The abundance of *Microcystis* (Fig. 2c) was then examined and correlated with changes in particulate  $^{15}\text{N}$  (Fig. 2a) and in C:N ratios (Fig. 2b). *Microcystis* was first detected in very low numbers in the surface waters during May 1977. These colonies failed to develop and *Microcystis* colonies present in May could not have been solely responsible for the total particulate  $^{15}\text{N}$  noted. This May 1977 *Microcystis* (based on cell volume estimates and a  $^{15}\text{N}$  enrichment of 1.33 atom % excess  $^{15}\text{N}$ ) accounted for <25% of the observed water column  $^{15}\text{N}$  concentration. Together with the high C:N ratio this suggested that the labelled material was largely cell debris derived from the sediment surface. Also, at that time the colonial chrysophyte *Uroglenopsis americana*<sup>11</sup> developed. This alga, which was absent from the phytoplankton the previous year, may exist, like other chrysophytes, as cysts on the sediment surface until germination, possibly obtaining some  $^{15}\text{N}$  from sediment pore water and then moving into the water column. In late July *Microcystis* became clearly detectable in the water column and was concentrated at 8.5 m, the site of highest  $^{15}\text{N}$  concentration. In August, *Microcystis* developed in the surface waters and its presence there correlated with the presence of particulate  $^{15}\text{N}$

**Fig. 2** a, The distribution of particulate  $^{15}\text{N}$  in the water column and sediment of a Lund enclosure in Blelham Tarn from March 1977 to September 1977. ■, >80; ▨, 50–80; ▩, 35–50; □, 25–35; □, 0–25 (all ng per l). b, The distribution of particulate organic carbon-to-nitrogen ratio of water column material of a Lund enclosure in Blelham Tarn from March 1977 to September 1977. □, >12:1; □, 12:1–11:1; ▨, 11:1–9:1; ▩, <9:1. c, The distribution of *M. aeruginosa* colonies in the water column of a Blelham Tarn enclosure from March 1977 to October 1977. ■, >7; ▨, >3; ▩, 1–3; □, 0.1–1; □, <0.1 (per ml). The colonies were counted by sedimentation and microscopy<sup>14</sup>.

(the *Microcystis* biomass then could easily account for the total particulate  $^{15}\text{N}$  in the epilimnion) although, because of its undoubted assimilation of unlabelled nitrogen during growth, the  $^{15}\text{N}$  enrichment of *Microcystis* decreased. In late September *Microcystis*, like the particulate  $^{15}\text{N}$ , sedimented.

The above data collectively provide evidence that *Microcystis* overwinters on the sediment surface and serves as an inoculum for the following year's epilimnetic growth.

We thank the ARC and NERC for support and Dr J.W.G. Lund for helpful advice and encouragement.

## Explanation of sterility in $t^x t^y$ male mice

Michael J. Tucker

Department of Zoology and Comparative Physiology,  
University of Birmingham, PO Box 363, Birmingham B15 2TT, UK

The lethal ' $t$  alleles' of the T complex on mouse chromosome 17 (refs 1, 2) have been assigned to six complementation groups (the definitive classes being  $t^0$ ,  $t^9$ ,  $t^{12}$ ,  $t^{w1}$ ,  $t^{w5}$  and  $t^{w73}$ ), each causing embryonic death at a particular stage. Intercomplementation heterozygotes ( $t^x t^y$ ) show 'partial' complementation, so that only some  $t^x t^y$  offspring survive<sup>3,4</sup>. These survivors appear morphologically normal; indeed the females, being fertile, seem entirely normal. The  $t^x t^y$  males, however, are sterile. Among the reasons given for this sterility in some  $t^x t^y$  males are low motility of the  $t^x t^y$  spermatozoa<sup>5</sup>, and an inability to effect fertilization either *in vitro* or *in vivo* even when already present at the site of fertilization<sup>6,7</sup>. Spermatozoa from sterile  $t^x t^y$  males were reported to be apparently present in 'normal' numbers in the uterus, although actual ejaculate numbers have not been quoted for these, or indeed for normal fertile males<sup>5–8</sup>. In the human, typical ejaculate counts of less than  $20 \times 10^6$  spermatozoa, where the normal ejaculate contains  $100\text{--}250 \times 10^6$ , are judged to indicate clinical sterility<sup>9</sup>. The comparison of numbers of spermatozoa<sup>10</sup> ejaculated into the female tract by sterile  $t^6 t^{w5}$ ,  $t^6 t^{w32}$  and  $t^{w5} t^{w32}$  (all 'strong' mutations<sup>2</sup>) and control mice clearly shows an even greater oligozoospermia (about 100 times less than controls) occurring in the  $t^x t^y$  males.

Balanced lethal stocks of  $Tt^6$ ,  $Tt^{w5}$  and  $Tt^{w32}$  mice are maintained in the Department of Zoology at the University of Birmingham;  $t^x t^y$  tailed males were produced from crosses between these tail-less stocks ( $Tt^x \times Tt^y$ ). I investigated the numbers of spermatozoa ejaculated by sterile  $t^x t^y$  and control males by mating them with females at times ranging from 2 h before until 4 h after ovulation. Ovulating  $++$ (C3H),  $T+$ ,  $++$  and  $Tt$  females aged 2–10 months were used. (No differences were observed between results from induced or naturally ovulating females of differing ages or genotypes.) Females were killed as soon as a vaginal plug was seen (30 min observations). Control females were artificially inseminated with known

numbers of spermatozoa. The uterus and 'plugged' vagina were removed complete, after the ovarian end of the uterine horns had been ligatured, into a small (50 mm) Petri dish with as little blood as possible, and flushed with phosphate-buffered saline (PBS, Oxoid Dulbecco A) from a syringe and 21-gauge needle. The uterus was cut open, washed and scraped gently to transfer all spermatozoa to the wash-medium. All medium was taken up into 10 ml PBS and this was centrifuged at 250g for 15 min. The pellet was resuspended by gentle agitation into a further 10 ml PBS; 0.02-ml drops of this suspension were spotted out and air-dried on clean, marked slides. The dried spots were stained for 1 min in Wells and Awa stain<sup>11</sup>, air-dried and mounted in DPX (Hopkins and Williams Chemicals). All spermatozoa in each spot were counted in order to calculate the number in the 10 ml PBS, which was assumed to be the number ejaculated. When a visual estimate suggested a count greater than 1,000 per drop, the spermatozoa in 10 random  $\times 40$  objective fields (area  $0.16 \text{ mm}^2$ ) were counted and used to calculate total numbers in the dried drop of known size. The area of the spot was measured either by taking two diameter measurements at  $90^\circ$  where the spot was circular, or by making a trace on fine graph paper to calculate the area where the spot was misshapen. This was done to ensure standard treatment of all samples. I checked the multi-field count method by further diluting sperm suspensions and counting every sperm in each spot (diluted to contain 100–1,000 spermatozoa per drop). That gave numbers in agreement with the counts from the spots of lesser dilution ( $<10\%$  error). Table 1 shows the recovery of artificially inseminated spermatozoa, and makes possible estimation of the efficacy of the flushing technique; Table 2 shows the recovery of spermatozoa from females mated to control and  $t^x t^y$  males.

Spermatozoa from these control males were stripped from vasa deferentia and epididymides into warm ( $37^\circ\text{C}$ ) PBS. 0.05–0.10-ml sperm suspension was carefully injected per cervix as soon as possible (5–8 min) into etherized, oestrous females, and samples were diluted for counting to estimate the number of spermatozoa injected per female. Females were killed within 10 min of insemination, by cervical dislocation, and the uteri were exposed. Cervices were clamped and the uteri flushed as described in the text. Sperm numbers are given as log means  $\pm$  s.d. as recommended by Cohen<sup>10,12</sup>, and the linear values are also presented.

Recovery of spermatozoa from artificially inseminated females was relatively successful considering the difficulty of attempting to deposit known numbers of spermatozoa into the uterus. On the worst interpretation of the figures, recovery was usually 85% (the very worst was 43%). So the estimates of numbers of ejaculates from control and  $t^x t^y$  mice can be assumed to be at least as representative. The numbers assessed for C57BL males are close to previous estimations<sup>12</sup>, but are higher than those obtained by electroejaculation<sup>14</sup>. The figures for the  $t^x t^y$  mice of all three types are very variable between males, and even, to some extent, between copulations by one

| $t^6 t^{w32}$           | 1              | 3.79 (7,000) <sup>†</sup>                             | $+ + C57BL$   | 1              | $7.14 \pm 0.06$ (13.87 $\pm$ 1.8)                                    |
| $t^{w5} t^{w32}$        | 2              | $4.88 \pm 0.51$ (100,000 $\pm$ 98,000)                | $+ + C57BL$   | 2              | $6.86 \pm 0.04$ (7.17 $\pm$ 0.6)                                     |
|                         |                |   | $+ t^{w5}$    | 1              | $7.23 \pm 0.06$ (16.77 $\pm$ 2.5)                                    |

Female mice were either induced to ovulate (5 IU follicle stimulating hormone followed 48 h later by 5IU human chorionic gonadotropin; ovulation assumed to occur 13 h later<sup>13</sup>), or used when naturally ovulating as assessed by vaginal smear test.  $T+$  and  $+t$  mice were obtained as  $F_1$  from  $C57BL \times +t$  crosses. The  $t^x t^y$  males were considered sterile if they were run with five known-fertile females for 4 weeks or more without pregnancies (five 'mating units'<sup>4</sup>).

\* Standard deviations of pooled counts per mating where the s.d. of each count <20% of mean; except where only one count is given, then the s.d. of that count is shown.

<sup>†</sup> These counts were based on very few (<20) spermatozoa per spot.

<sup>‡</sup> Known fertile control males.

male. However, they are at least two orders of magnitude lower than the figures from the control males. In the human just one order of magnitude difference seems to confer a state of clinical sterility, so this hundredfold difference would adequately explain the sterility of these  $t^x t^y$  males.

In addition to the other suggested causes of the sterility<sup>5-7</sup>, the extreme  $t^x t^y$  oligozoospermia reported here presents a convincing explanation; it is tempting to consider this as the chief cause, with reduced motility and lack of fertilizability being secondary phenotypic expressions arising from the infertile state<sup>15</sup>. In this simple solution to the  $t^x t^y$  sterility it is not necessary to invoke altered sperm surface antigens interacting within the female<sup>16</sup>; the answers appear to lie in the course of spermatogenesis, which is in accordance with and extends the suggestion<sup>17</sup> that events before mating affect  $t^x t^y$  fertility. Preliminary studies so far indicate fewer spermatozoa present in the epididymides and vasa deferentia of  $t^x t^y$  males compared with controls<sup>18</sup>. It is to be hoped that further work will elucidate the actual processes resulting in this severe oligozoospermia found in these heterozygous  $t^x t^y$  male mice.

I thank Dr Jack Cohen for helpful criticism. This research was supported by a studentship from the SRC.

## Molecular analysis of the genetic relationship of *trans* interacting factors at the T/t complex

Althea K. Alton, Lee M. Silver, Karen Artzt & Dorothea Bennett

Laboratory of Developmental Genetics, Sloan-Kettering Institute, 1275 York Avenue, New York, New York 10021

The T/t complex is an extensive genetic region proximal to the H-2 complex on mouse chromosome 17, with multiple effects on embryonic development, spermatogenesis and recombination<sup>1-3</sup>. Recently, two-dimensional gel analysis of testicular cell proteins identified a gene within the T/t complex that codes for a major cell surface-associated protein, p63/6.9 (ref. 4). The wild-type gene, *Tcp-1*<sup>b</sup>, codes for a 63,000-molecular weight protein (p63/6.9b), whereas a mutant allele, *Tcp-1*<sup>a</sup>, which occurs in all intact *t* haplotypes, codes for a more acidic form of the protein (p63/6.9a). Analysis of partial *t* haplotypes obtained from rare recombination events showed that *Tcp-1*<sup>a</sup> correlated completely with the tail interaction factor *t*<sup>T</sup>, which is thought to be a genetic allele of *T*, thus raising the possibility that the locus of *T* codes for the p63/6.9 protein. We report here that the p63/6.9 proteins produced by seven chromosomes carrying independently derived dominant mutations at the locus of *T* are all indistinguishable from the wild-type form; thus, the cumulative data indicate that the *Tcp-1* gene is most probably not at the locus of *T*.

The T/t complex was originally defined by the dominant mutation *Brachyury* (*T*), which shortens the tails of heterozygotes and is lethal at 10.5 days of gestation when homozygous. Recessive lethal *t* haplotypes are found at high frequency in wild mice and are identified by their interaction with *T* to produce a tailless phenotype. Recombination data demonstrate that naturally occurring *t* haplotypes are separable into at least two well defined genetic factors (see Fig. 1): a proximal factor, *t*<sup>T</sup>, is allelic to and interacts in *trans* with *T* to produce taillessness; a distal factor, *t*<sup>lethal</sup>, results in embryonic death when it is homozygous. Other data indicate that the *t* haplotype may be

**Fig. 1** *a*, Mouse chromosome 17 and relevant markers. Genetic distance between markers is given in centimorgans. *b*, *t* Haplotype showing the separation of *t* factors.

separated into several other factors including those factors responsible for male sterility and distorted segregation ratios<sup>5</sup>.

Partial *t* haplotypes, recovered from recombination events, were used to map the *Tcp-1* gene: *Tcp-1*<sup>a</sup> was not associated with the one available partial haplotype (*t*<sup>h17</sup>) carrying only the *t*<sup>lethal</sup> factor, but correlated completely with the presence of the tail interaction factor, *t*<sup>T</sup>, in a variety of partial haplotypes examined. As *t*<sup>T</sup> and *T* behave as genetic alleles, the simplest explanation for the data was that the p63/6.9 protein was the direct gene product of the locus of *T*. However, the form of p63/6.9 produced by the one *T* mutation examined (*Brachyury*) was indistinguishable by two-dimensional gel analysis from wild type.<sup>4</sup> Nevertheless, as two-dimensional gel analysis is capable of defining only about one-third of all point mutations, the possibility remained that the locus of *T* codes for the p63/6.9 protein.

Seven independently derived dominant tail mutations at the locus of *T* have been analysed here (Table 1). These include two radiation-induced mutations and five spontaneous mutations which occurred in laboratory stocks. Of the five spontaneous mutations at *T*, two seem to be deletions of a portion of chromosome 17 including the *T* locus and another locus, *quaking* (*qk*). All *T*-locus mutations meet the following criteria: (1)

they are dominant mutations mapped to the *T/t*-complex region of chromosome 17, and are lethal when homozygous; (2) they interact with *t* to produce a tailless phenotype in *T/t* individuals; (3) they fail to complement one another and hence *T*<sup>x</sup>/*T*<sup>y</sup> individuals die during embryonic development.

The expression of the p63/6.9 protein in heterozygotes for seven independent *T*-locus mutations was analysed by two-dimensional gel electrophoresis of radio-labelled testicular cell proteins (Fig. 2, Table 2). Animals which carried *T*, *T*<sup>hp</sup>, *T*<sup>Wis</sup>, *T*<sup>J</sup>, *T*<sup>c</sup> and *T*<sup>OR4</sup> opposite a chromosome with a wild-type *Tcp-1*<sup>b</sup> allele expressed a distinct p63/6.9b protein spot, but showed no additional spots (relative to known *Tcp-1*<sup>b</sup> homozygotes) in the p63/6.9 region of two-dimensional gels. In each case, this result indicates that the chromosome opposite *Tcp-1*<sup>b</sup> either expresses p63/6.9b or does not express any form of the p63/6.9 protein.

To distinguish between these two possibilities, we analysed the protein patterns of mice carrying each of these mutations opposite a chromosome carrying a *Tcp-1*<sup>a</sup> allele. Animals which carried *T*, *T*<sup>Wis</sup>, *T*<sup>J</sup>, *T*<sup>c</sup> and *T*<sup>OR4</sup> and a *Tcp-1*<sup>a</sup> allele all expressed both p63/6.9b and p63/6.9a. Therefore, each of these *T*-locus mutations expresses the wild-type form of the p63/6.9 protein. As described previously, mice with a *T*<sup>hp</sup>/*Tcp-1*<sup>a</sup> genotype express only p63/6.9a (ref. 4). Therefore, chromosomes with the *T*<sup>hp</sup> deletion do not have a functional *Tcp-1*<sup>a</sup> gene.

The apparent deletion *T*<sup>Orl</sup> was analysed for *Tcp-1* gene expression. *T*<sup>Orl</sup>/*Tcp-1*<sup>a</sup> mice express both p63/6.9b and p63/6.9a. This indicates that the *T*<sup>Orl</sup> deletion does not cover the *Tcp-1* gene. However, *T*<sup>Orl</sup>/*Tcp-1*<sup>b</sup> mice also express both p63/6.9b and p63/6.9a. These data imply that the *T*<sup>Orl</sup> chromosome, far from containing a deletion of *Tcp-1*, actually possesses both the *Tcp-1*<sup>b</sup> and *Tcp-1*<sup>a</sup> alleles. Further analysis of this chromosome is in progress.

The *Tcp-1* gene codes for a major cell surface-associated protein, p63/6.9. Two structural alleles of this gene have been

**Fig. 2** *A*, Complete two-dimensional fluorograph of Nonidet P40-soluble proteins from *T*<sup>c</sup>/*t*<sup>w73</sup> testicular cells. *b*, p63/6.9b; *a*, p63/6.9a. The basic side of the gel is on the left. *B-E*, The p63/6.9 regions of fluorographs are shown for the following genotypes: *B*, *T*<sup>Wis</sup>/+; *C*, *T*<sup>Wis</sup>/*t*<sup>w73</sup>; *D*, *T*<sup>OR4</sup>/+; *E*, *T*<sup>OR4</sup>/*t*<sup>w18</sup>. Testicular cells were isolated essentially as described by Romrell *et al.*<sup>12</sup> as modified by Silver *et al.*<sup>4</sup>. Cells were labelled in medium containing 200–250  $\mu$ Ci ml<sup>-1</sup> <sup>35</sup>S-methionine, for 4–5 h at 34 °C. Cells were washed and lysed at a concentration of 10<sup>7</sup> cells ml<sup>-1</sup> with phosphate-buffered saline containing 1% Nonidet P40, 2 mM methionine and 1 mM phenylmethylsulphonyl-fluoride. Nonidet P40-soluble proteins were obtained after centrifugation at 15,000g at 4 °C for 60 min and were stored at -80 °C. Proteins were separated according to the procedure described by O'Farrell and O'Farrell<sup>13</sup> as modified by Silver *et al.*<sup>4</sup>.

**Table 1** Origin of the various *T* mutations

| <i>T</i> Mutation                                    | Origin                               | Ref.                             |

|  |                                      | 11                               |

identified. All wild-type chromosomes carry *Tcp-1<sup>b</sup>* whereas all naturally occurring *t* haplotypes carry *Tcp-1<sup>a</sup>*. As *Tcp-1<sup>a</sup>* and the *t<sup>T</sup>* allele of the *T* locus seemed to be completely correlated<sup>4</sup>, we sought to determine whether the *Tcp-1* gene and the locus of *T* were identical. Of seven independently derived *T*-locus mutations examined, six allowed expression of a form of p63/6.9 which seems to be identical to the wild-type p63/6.9. The seventh, *T<sup>hp</sup>*, acted as a null allele of *Tcp-1* (*Tcp-1<sup>a</sup>*).

At least 33% of all single base pair substitutions will result in an alteration in protein charge that can be readily detected by standard isoelectric focusing techniques<sup>6</sup>. If we take a conservative estimate, 66% of all single base pair substitutions go undetected (that is, those resulting in a neutral-to-neutral amino acid change). If we assume that the *Tcp-1* gene is at the locus of *T*, the probability that in six independent mutational events at *T* such a shift has occurred and that it remains undetected is (0.66)<sup>6</sup>. The probability of detecting at least one such shift is 1 - (0.66)<sup>6</sup> or 92%. Because, in fact, no shifts were detected, we can say with 92% probability that the *Tcp-1* gene is separate from the locus of *T*. This view is compatible with other genetic evidence. *T<sup>hp</sup>* is known to be a deletion covering at least the 3-centimorgan region between and inclusive of *T* and *qk* as well as the locus of *Tcp-1*. *T<sup>Orl</sup>* seems to be a deletion covering at least the same 3-centimorgan region, but *Tcp-1* is not within the deletion. Thus, the *Tcp-1* gene must be localized to the region of the *T<sup>hp</sup>* deletion either proximal to *T* or distal to *qk* and, therefore, cannot be equivalent to *T*. Previous results have demonstrated that the *Tcp-1* gene is separate from the loci of *qk*, *low*, *tf* and *t<sup>lethal</sup>* (see Fig. 1 and ref. 4).

We have demonstrated that the *Tcp-1* gene is separate from the locus of *T*; however, as *Tcp-1<sup>a</sup>* is completely correlated with the presence of *t<sup>T</sup>*, the possibility still exists that p63/6.9a is a product of *t<sup>T</sup>*. If this proves to be the case, then *T* and *t<sup>T</sup>* cannot, as previously assumed, be alleles at the same locus. Although *T* and *t<sup>T</sup>* are not separable by recombination, one must remember

that one of the effects of *t* haplotypes is the suppression of recombination along chromosome 17. *T* and *t<sup>T</sup>* interact in *trans* to produce taillessness, but it is possible that *trans* interactions can occur even between two interacting factors at separate loci. Until the precise relationship between *t<sup>T</sup>* and *Tcp-1* can be determined, one cannot comment on the validity of the assumption that *T* and *t<sup>T</sup>* are alleles at the same locus.

Although it is possible that the p63/6.9 protein may be associated with some other property of the *T/t* complex, such as segregation distortion or sterility, for which others had suggested factors existed<sup>5</sup>, our data do not fit the distribution of any known *T/t*-complex factor other than *t<sup>T</sup>*.

This work was supported in part by NCI core grant CA-08748, grants CA 21651 and HD 10668, and research contract EV04159. A.K.A. is a pre-doctoral fellow at the Sloan-Kettering Division of the Cornell Graduate School of Medical Sciences and received support from the American Cancer Society institutional grant IN-114. We thank Dr T. Alton for his help with the figures, and Drs H. Axelrod, P. McCormick and T. Alton for their critical reading of the manuscript.

## Effect of striatal cells on *in vitro* maturation of mesencephalic dopaminergic neurones grown in serum-free conditions

Umberto di Porzio, Marie-Christine Daguet, Jacques Glowinski & Alain Prochiantz

INSERM U.114, Collège de France, 11 place Marcelin Berthelot, 75231 Paris Cedex 05, France

It is well documented that target cells can regulate the morphological and biochemical development of peripheral afferent neurones<sup>1,2</sup>, but little is known about the existence of such regulatory mechanisms in the central nervous system. We therefore investigated previously the influence of striatal target cells on the maturation *in vitro* of nigrostriatal dopaminergic neurones, which survive in culture for more than 5 weeks, develop dense arborizations and both take up <sup>3</sup>H-dopamine (DA) by a high-affinity specific process and synthesize <sup>3</sup>H-DA from <sup>3</sup>H-tyrosine<sup>3</sup>. Furthermore, depolarization by potassium or veratridine stimulates the release of DA through a calcium-dependent mechanism and tetrodotoxin prevents the veratridine-evoked release of the transmitter<sup>4</sup>. Both the number of <sup>3</sup>H-DA uptake sites and the capacity for <sup>3</sup>H-DA synthesis were at least doubled when the neurones were cultured with target cells from the striatum<sup>3</sup>. To determine whether glial cells which proliferate in serum-complemented medium are partly responsible for the maturation of dopaminergic neurones and/or for the effect of striatal cells, we have now repeated the experiment using serum-free medium in which virtually pure neuronal populations can be obtained<sup>5-7</sup>. The reduction in the number of glia did not affect either the maturation of dopaminergic cells alone, or the effect of striatal cells. Autoradiographic analysis of the number of dopaminergic cells strongly suggests that the stimulatory effect is related to increased capacities of <sup>3</sup>H-DA uptake and synthesis per dopaminergic neurone.

**Table 1** Composition of various serum-free media and their effects on dopaminergic cell survival

|                          | Medium 1 | Medium 2 | Medium 3 |
|--------------------------|----------|----------|----------|
| Basal medium             | —        | +        | —        |
| Proteins, hormones, salt | +        | +        | +        |
| Conditioned medium       | +        | —        | +        |
| Survival time            | ≥14 days | ≤10 days | ≥14 days |

In all cases, cells were grown on non-irradiated collagen plus polyornithine as substrate. Basal medium was as described in Fig. 1a legend; proteins, hormones, salt refer to transferrin, insulin, progesterone, putrescine, selenium salt (see text for concentrations); conditioned medium 1 was basal medium incubated for 48 h with cells (fibroblasts or total brain cells) previously grown with a serum-complemented medium for 1–4 weeks; conditioned medium 3 was medium obtained after 8 days from total brain cells directly plated and grown with medium 2.

Preliminary experiments indicated that the use of non-irradiated collagen markedly reduced the overall population of glial cells when mesencephalic cells of 13-day-old mouse embryos were cultured with serum. Furthermore, autoradiography of the cultures (Fig. 1c) after a 48-h pulse of  $^3\text{H}$ -thymidine (during days 3–5) revealed that the number of labelled cells with large nuclei (presumptive astrocytes<sup>8</sup>) was only 2.3% ( $742 \pm 109$ ,  $n = 3$ ) of that found in cultures grown on UV-irradiated collagen plus polyornithine ( $31,600 \pm 1,500$ ,  $n = 3$ ). To eliminate glial elements further, mesencephalic cells were dissociated in a serum-free medium and then plated on non-irradiated collagen plus polyornithine in a conditioned medium obtained by 48-h incubation of the serum-free medium with monolayers of primary cultures of embryonic cells from whole mouse brain or of fibroblasts previously grown with serum. Thereafter, this conditioned medium was supplemented with  $100 \mu\text{g ml}^{-1}$  transferrin (Sigma),  $25 \mu\text{g ml}^{-1}$  insulin (Sigma),  $2 \times 10^{-8}$  M progesterone (Sigma),  $6 \times 10^{-5}$  M putrescine (Sigma) and  $3 \times 10^{-8}$  M selenium salt (Merck), and filtered (Millex; Millipore). In this medium (medium 1), the number of labelled glial cells (estimated as above) was only 0.06% ( $20 \pm 14$ ,  $n = 3$ ) of that found with serum using UV-irradiated collagen plus polyornithine (Fig. 1a, b). In medium 1, despite the virtual absence of glial cells, the overall neuronal population survived for 2–4 weeks according to the experiments (Table 1). The incubation of mesencephalic cells with exogenous  $^3\text{H}$ -DA allowed the autoradiographic visualization of dopaminergic neurones, which exhibit numerous varicose fibres (Fig. 1d). As illustrated by Table 2, the capacities of  $^3\text{H}$ -DA uptake and of  $^3\text{H}$ -DA synthesis from  $^3\text{H}$ -tyrosine increased with time in culture (up to 15 days at least). Medium 1 is thus preferable to the serum-complemented medium used in our previous study because in the latter case  $^3\text{H}$ -DA uptake and synthesis did not increase between days 8 and 15 in mesencephalic cultures. However, as in the presence of serum<sup>3</sup>, the extent of  $^3\text{H}$ -DA uptake or synthesis in mesencephalic cultures grown with medium 1 varied between experiments; this did not seem to be related to the cell type used to condition the medium.

When mesencephalic cells were cultured in medium 1 in the presence of striatal target cells from 15-day-old embryos (co-cultures), the glial cell population was still negligible ( $26.5 \pm 2$ ,  $n = 3$ ). Nevertheless, as revealed by the enhanced capacities of  $^3\text{H}$ -DA uptake and synthesis in co-cultures, the striatal cells stimulated the maturation of the mesencephalic dopaminergic neurones (Table 2). These stimulatory effects varied (1.5–3 times) between experiments but were always significant, at both 8 and 15 days. These effects cannot be attributed to the higher cell concentration used in co-cultures ( $2.5 \times 10^6$  cells per dish) because  $^3\text{H}$ -DA uptake in mesencephalic cultures alone is directly proportional to the number of cells plated (between  $1 \times 10^6$  and  $3.5 \times 10^6$  cells, results not shown).

Complementary experiments were carried out to determine whether the development of the dopaminergic neurones and their enhanced maturation in the presence of striatal cells were dependent on the occurrence in medium 1 (Table 1) of

**Fig. 1** a, Thirteen-day-old mouse embryonic mesencephalic cells were dissociated in a mixture of minimum essential medium and nutrient mixture F-L2 (both Gibco, 1:1) complemented with  $3.3 \times 10^{-2}$  M glucose,  $2 \times 10^{-3}$  M glutamine and  $0.3 \times 10^{-2}$  M sodium bicarbonate without serum (basal medium). Cells ( $1.5 \times 10^6$  per dish) were then plated on UV-irradiated collagen plus polyornithine and grown in basal medium plus 7.5% fetal calf serum (Irvine Scientific) as previously described<sup>1</sup>. Arabinosylcytosine ( $10^{-5}$  M, Sigma) was added at day 5, the medium (2 ml) was replaced at day 7 and thereafter weekly. The extensive development of both neurones and glial cells at day 5 can be seen.  $\times 187$ . b, Mesencephalic cells were dissociated as above, plated on non-irradiated collagen plus polyornithine and grown in 1 ml of medium 1 (a serum-free, conditioned medium prepared as described in the text); cells were not exposed to arabinosylcytosine and the medium was not renewed. In these conditions, in contrast to that observed in a, the development of glial cells was impaired. The development of neurones in the virtual absence of glial cells at day 5 is seen.  $\times 187$ . c, Visualization by autoradiography at day 5 of glial cell nuclei labelled by incubating mesencephalic cells for 48 h between days 3 and 5 with  $9 \times 10^{-7}$  M  $^3\text{H}$ -thymidine ( $28 \text{ Ci mmol}^{-1}$ , CEA) added to the culture medium.  $\times 180$ . After three washes with cold phosphate-buffered saline (PBS), the cells were fixed for 1 h at  $4^\circ\text{C}$  with 2.5% glutaraldehyde (Taab Laboratories) in PBS, rinsed four times with cold PBS, air dried and covered with Ilford K5 emulsion. Autoradiograms were developed 1 week later using Kodak Dektol. d, Visualization of labelled dopaminergic neurones at day 8 by autoradiography.  $\times 183$ . Cells were incubated at  $37^\circ\text{C}$  for 1 h with  $5 \times 10^{-7}$  M  $^3\text{H}$ -DA ( $9.9 \text{ Ci mmol}^{-1}$ , NEN) in 1 ml PBS complemented with  $10^{-3}$  M magnesium,  $10^{-3}$  M calcium and  $3.3 \times 10^{-2}$  M glucose. Cells were then washed and processed for autoradiography as described in c. No labelling was seen when the incubation was carried out at  $0^\circ\text{C}$ . Incubation at  $37^\circ\text{C}$  in the presence of  $5 \times 10^{-6}$  M desmethyl-imipramine (Geigy) or  $10^{-6}$  M fluoxetine (Lilly), drugs known to inhibit  $^3\text{H}$ -DA uptake into noradrenergic and serotonergic neurones respectively, did not modify the number of labelled cell bodies. This number was reduced to 5% of control values when the incubation was performed in the presence of  $5 \times 10^{-6}$  M benztropine (Merck), a potent inhibitor of  $^3\text{H}$ -DA uptake into dopaminergic nerve cells.

substances of cellular origin or of contaminating serum components released into the medium during the 48-h conditioning period. Mesencephalic cell cultures or co-cultures with striatal cells were thus directly plated in medium 2, which consisted of a non-conditioned serum-free basal medium supplemented with hormones, proteins and salts as above (Table 1). In this medium, the development of glial cells was equally impaired ( $8.5 \pm 3.5$ ,  $15 \pm 4.2$ ,  $n = 3$ ,  $^3\text{H}$ -thymidine-labelled cells in cultures and co-cultures, respectively). The dopaminergic neurones could be characterized as in medium 1 by autoradiography and by the estimated capacities for  $^3\text{H}$ -DA uptake and synthesis. However,  $^3\text{H}$ -DA uptake was lower than that observed with medium 1 and the survival of the mesencephalic neurones never exceeded 10 days. Nevertheless, the stimulatory effect of the striatal target cells on  $^3\text{H}$ -DA uptake and synthesis was present at 8 days, as observed with medium 1 (Table 2). From these results we conclude that the use of a conditioned medium containing traces of serum components is not required for the influence of target striatal cells on dopaminergic neurones, although it favours their overall development.

A possible role of serum contaminants in the improved survival of cultures and co-cultures in medium 1 over that in medium 2 was excluded by studies with a third type of conditioned medium. Dissociated cells from the whole brain of 15-day-old mouse embryos were directly plated in the serum-free medium 2 and grown for 8 days. The medium was then removed, filtered, further complemented with proteins, hormones and salts (as described for media 1 and 2) and used as conditioned medium (medium 3, Table 1). Results comparable with those reported for experiments performed with medium 1 were obtained: absence of glial cells, satisfactory development of the neuronal populations including the dopaminergic neurones, which survived for 2 weeks at least, and facilitated maturation of the dopaminergic neurones in the presence of striatal cells, as revealed by measurement of  $^3\text{H}$ -DA uptake at 8

and 15 days (Table 2). Thus, substances of cellular origin are apparently responsible for the longer survival of neurones in medium 1. Furthermore, these substances could originate from neurones because medium 3 was prepared in conditions impairing the development of glial cells.

**Table 3** Mean value of  $^3\text{H}$ -dopamine uptake per dopaminergic cell at 8 days in medium 1

|                 | -STR            | +STR              |
|-----------------|-----------------|-------------------|
| Expt 1          |                 |                   |
| Uptake          | $6,143 \pm 924$ | $9,555 \pm 661^*$ |
| Cell number     | $1,556 \pm 574$ | $1,495 \pm 276$   |
| Uptake per cell | 3.9             | 6.4               |
| Expt 2          |                 |                   |
| Uptake          | $6,207 \pm 523$ | $9,134 \pm 561^*$ |
| Cell number     | $1,880 \pm 416$ | $1,207 \pm 118$   |
| Uptake per cell | 3.3             | 7.7               |

$^3\text{H}$ -dopamine uptake in cultures (-STR) and co-cultures (+STR) was estimated as described in Table 2 legend (mean of four determinations). Sister cultures and co-cultures were used to count the number of labelled dopaminergic cell bodies after autoradiography as described in Fig. 1d legend. Results are the mean  $\pm$  s.e.m. of triplicates.  $^3\text{H}$ -DA uptake per cell is expressed as c.p.m. per cell.

\* Difference between values obtained with cultures and co-cultures is significant ( $P < 0.05$ ).

Due to the marked reduction of the glial cell population in the various experimental conditions used, it is unlikely that glial cells contribute to the stimulatory effect of striatal cells on the development of mesencephalic dopaminergic neurones. However, it is just possible that a minor population of striatal glial cells distinct from those evaluated by  $^3\text{H}$ -thymidine incorporation is still present and thus involved in the phenomenon observed.

To determine whether the stimulatory effect of striatal neurones on  $^3\text{H}$ -DA uptake and synthesis is related to a better survival or to an increased maturation of individual dopaminergic cells, the numbers of neurones labelled with  $^3\text{H}$ -DA in cultures and co-cultures were estimated on autoradiograms. The effects of various inhibitors of amine uptake in aminergic neurones on the number of labelled cells indicated that the neurones labelled in these conditions corresponded to dopaminergic cells (Fig. 1d legend). By counting all labelled dopaminergic cell bodies, analysis of several experiments carried out with medium 1 indicated that after 8 days in culture, the total number of dopaminergic cells was not modified by the presence of striatal cells (Table 3). Similar observations were made with media 2 and 3 (data not shown). These results suggest an increased development of individual dopaminergic neurones in co-cultures and confirm previous estimations made after histochemical visualization of dopaminergic neurones grown in serum-complemented medium<sup>3</sup>.

Autoradiograms also revealed that some dopaminergic neurones were more intensely labelled than others. This may be related to the presence in the cultures of subpopulations of dopaminergic cells involved in the formation of the various ascending dopaminergic pathways. It is not known whether these subpopulations of mesencephalic dopaminergic cells respond in a similar way to the influence of striatal neurones.

We draw three main conclusions from our study: (1) the mesencephalic dopaminergic neurones could develop when cultured in serum-free medium (conditioned or not), which markedly impaired the proliferation of glial cells; (2) the dopaminergic neurones survived for a longer time when the synthetic medium was conditioned in the presence of different cell types, indicating that diffusible cellular products are required for long-term survival; (3) in the virtual absence of glial elements the striatal cells exerted a stimulatory effect on the

**Table 2** Influence of striatal cells on  $^3\text{H}$ -DA uptake or synthesis in mesencephalic cells grown in various serum-free media

Mesencephalic (13-day-old) and striatal (15-day-old) mouse embryonic cells were dissociated in basal medium as described in Fig. 1a legend, plated on non-irradiated collagen plus polyornithine and grown in 1 ml of medium 1, 2 or 3 (see Table 1 and text). Cultures (-STR) were obtained by plating  $1.5 \times 10^6$  mesencephalic cells per dish;  $1.5 \times 10^6$  mesencephalic cells and  $1 \times 10^6$  striatal cells per dish were used in co-cultures (+STR). In several experiments  $^3\text{H}$ -DA uptake or synthesis was estimated in 8- and/or 15-day-old cultures and co-cultures. Cells were incubated with  $5 \times 10^{-8}$  M  $^3\text{H}$ -DA ( $9.9 \text{ Ci mmol}^{-1}$ ) for 15 min or with  $1.5 \times 10^{-6}$  M  $^3\text{H}$ -tyrosine ( $52.5 \text{ Ci mmol}^{-1}$ , NEN) for 1 h at  $37^\circ\text{C}$  and then treated as described previously<sup>3</sup> to measure their  $^3\text{H}$ -DA content. Results expressed in c.p.m. are the mean  $\pm$  s.e.m. of four determinations, the yield of the counter for tritium being 40%. ND, not determined.

\* The difference between values obtained with cultures and co-cultures is significant using the Student's *t*-test ( $P < 0.05$ ).

maturation of individual dopaminergic neurones whatever the serum-free medium used (conditioned or not). Therefore, serum-free media should facilitate the characterization of the molecules and of the neuronal interactions that intervene in the survival of mesencephalic dopaminergic neurones and in their enhanced maturation in the presence of striatal target cells.

## The obligatory role of endothelial cells in the relaxation of arterial smooth muscle by acetylcholine

Robert F. Furchgott & John V. Zawadzki

Department of Pharmacology, State University of New York  
Downstate Medical Center, Brooklyn, New York 11203

Despite its very potent vasodilating action *in vivo*, acetylcholine (ACh) does not always produce relaxation of isolated preparations of blood vessels *in vitro*. For example, in the helical strip of the rabbit descending thoracic aorta, the only reported response to ACh has been graded contractions, occurring at concentrations above 0.1  $\mu$ M and mediated by muscarinic receptors<sup>1,2</sup>. Recently, we observed that in a ring preparation from the rabbit thoracic aorta, ACh produced marked relaxation at concentrations lower than those required to produce contraction<sup>3,4</sup> (confirming an earlier report by Jelliffe<sup>5</sup>). In investigating this apparent discrepancy, we discovered that the loss of relaxation by ACh in the case of the strip was the result of unintentional rubbing of its intimal surface against foreign surfaces during its preparation. If care was taken to avoid rubbing of the intimal surface during preparation, the tissue, whether ring, transverse strip or helical strip, always exhibited relaxation to ACh, and the possibility was considered that rubbing of the intimal surface had removed endothelial cells<sup>4</sup>. We demonstrate here that relaxation of isolated preparations of rabbit thoracic aorta and other blood vessels by ACh requires the presence of endothelial cells, and that ACh, acting on muscarinic receptors of these cells, stimulates release of a substance(s) that causes relaxation of the vascular smooth muscle. We propose that this may be one of the principal mechanisms for ACh-induced vasodilation *in vivo*. Preliminary reports on some aspects of the work have been reported elsewhere<sup>4,6</sup>.

Descending thoracic aortas were excised from white, male, New Zealand rabbits (2–3 kg), and trimmed free of adhering fat and connective tissue as previously described<sup>2</sup>. Transverse rings of 2.5-mm width were cut with scissors or with a special cutting device containing five parallel razor blades. A transverse strip was made by cutting across a ring. Strips and rings were mounted for isometric recording of tension in oxygenated Krebs–bicarbonate solution. Throughout the preparation and mounting of rings and transverse strips, the tissue was kept wet with Krebs solution, and special care was taken to avoid unintentional rubbing of the intimal surface against a foreign surface or itself.

Figure 1a, b shows typical records illustrating both the concentration-dependent relaxation by ACh of a ring and a transverse strip of aorta precontracted with noradrenaline (NA), and the loss of the relaxing response after rubbing of the intimal surface of each preparation. If care was taken not to over-stretch the preparation during the rubbing and to allow sufficient re-equilibration time (30–60 min) after the rubbing, the procedure did not lead to any loss of sensitivity to contracting agents; indeed, apparent sensitivity to ACh as a contracting agent is increased. Rubbing also had no effect on the sensitivity of aortic preparations to a variety of nonmuscarinic relaxing agents, including glyceryl trinitrate, sodium nitrite, sodium azide, adenosine, adenylic acid and isoprenaline, or to photorelaxation<sup>7</sup>.

The relaxation at lower concentrations of ACh, like the contraction at higher concentrations<sup>1,2</sup>, was highly sensitive to blockade by atropine. From the ratio of ACh concentrations giving equal relaxation with and without atropine (10  $\mu$ M, 30 min), the dissociation constant ( $K_B$ ) of the atropine–receptor complex was estimated to be  $0.35 \pm 0.04$  nM ( $n = 14$ ). This  $K_B$  value and the relative potencies of ACh, methacholine and carbachol (about 1, 0.3 and 0.1, respectively) in eliciting relaxation indicate that the receptor involved is of the muscarinic type. Physostigmine (0.3  $\mu$ M) did not significantly increase the sensitivity to ACh.

The range of concentration over which ACh produced graded relaxation in aortic preparations precontracted with NA was usually 0.01–1  $\mu$ M (Fig. 1). Occasionally, in preparations with higher than usual sensitivity to the contracting action of ACh, contraction would begin to supercede relaxation at 1  $\mu$ M. Half-maximal relaxation usually occurred between 0.03 and 0.10  $\mu$ M. Prolonged exposure to a fixed concentration of ACh usually resulted in some 'fade' of its relaxing effect. The degree of relaxation elicited by addition of a fixed concentration of ACh tended to decrease as the level of initial tonic contraction (tone) was increased.

ACh was about equally effective in relaxing contractions of the same magnitude produced by NA, histamine, serotonin, angiotensin or prostaglandin  $F_{2\alpha}$ . However, moderate to high contractions produced by increasing  $K^+$  in the Krebs solution (by adding 12–18 mM KCl) were less sensitive to ACh, showing maximal relaxation 10–50% of that of comparable NA-induced contractions. In two experiments in which the Krebs solution bathing the aortic rings was replaced by a ' $K_2SO_4$ –Krebs solution' (NaCl and  $NaHCO_3$  of the regular solution substituted for by equimolar concentrations of  $K_2SO_4$  and  $KHCO_3$ , respectively), the contractions obtained, which were ~75% of maximal NA-contractions, were relaxed about 20% by 1  $\mu$ M ACh. As the  $K_2SO_4$ –Krebs solution should completely depolarize all cells of the preparations, relaxation by ACh can apparently occur independently of membrane potential changes of the smooth muscle cells.

The fact that rubbing of the intimal surface, but not the adventitial surface, removed the capacity of aortic preparations to relax in response to ACh strongly suggested that the endothelial cells were necessary for the relaxation and that they were removed by the rubbing. To investigate this possibility, the intimal surfaces of variously treated preparations were examined microscopically *en face* after application of a silver staining procedure<sup>8</sup> which delineates endothelial cell borders, and also stains the subendothelial layer in areas where endothelial cells have been lost. Some typical photomicrographs are shown in Fig. 2. Unrubbed preparations in which ACh produced 80–100% relaxation of moderate tone had usually retained 60–75% of the endothelial cells by the end of an experiment. In 'inadequately' rubbed preparations it was not unusual to observe about 20% relaxation of moderate tone when only a few per cent of the endothelial cells were retained. When rubbing resulted in the complete loss of the relaxing response to ACh, there was always virtually a complete loss of endothelial cells. Thus, the staining procedure clearly showed that endothelial cells were required for relaxation by ACh. Preparations were

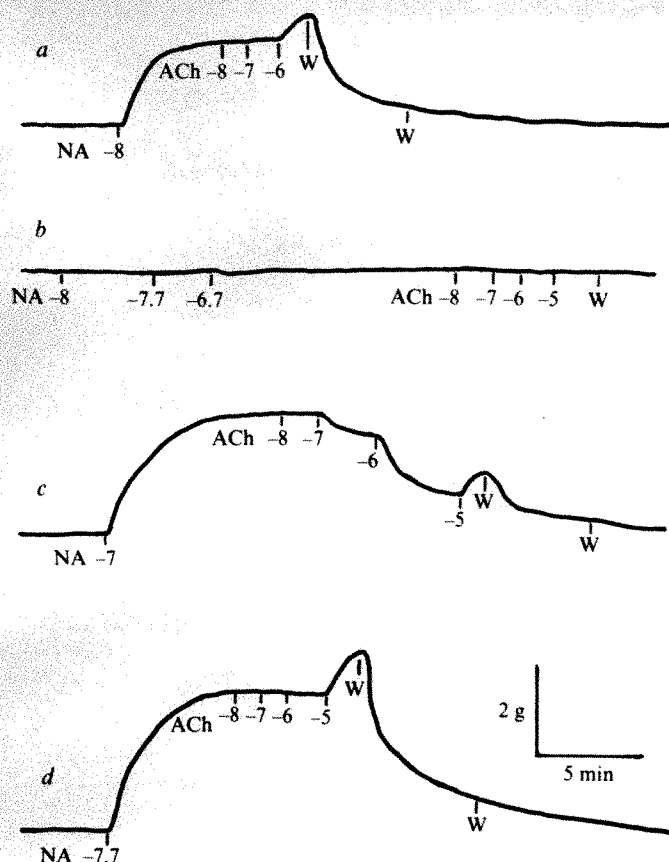

**Fig. 1** Loss of relaxing response of preparations of rabbit aorta to ACh after rubbing of the intimal surface or exposure to collagenase. Rings and transverse strips were mounted in all-glass 20-ml muscle chambers at 37 °C. The bathing fluid was Krebs solution of the following composition (mM): NaCl 118, KCl 4.8, CaCl<sub>2</sub> 2.5, MgSO<sub>4</sub> 1.2, KH<sub>2</sub>PO<sub>4</sub> 1.2, NaHCO<sub>3</sub> 24, glucose 11 and Na<sub>2</sub>-EDTA 0.03. It was continuously gassed with 95% O<sub>2</sub>-5% CO<sub>2</sub>. Two hooks of stainless steel wire (0.6-mm diameter), bent in a modified L-shape, were used to mount each ring. The short straight portion of each hook passed through the lumen of the ring. The lower hook was attached to the base of the muscle chamber, the upper to a strain gauge. For mounting each strip, two small lucite clips with jaws under spring tension were used. Hooks connected the lower clip to the base of the muscle chamber, and the upper clip to a strain gauge. All preparations were first equilibrated for at least 2 h, and basal tension was set to 2 g before drug additions. The records show the point at which each drug addition was made, and the corresponding cumulative concentration of the drug in the chamber after the addition, expressed as the log of the molar concentration. NA indicates noradrenaline; W indicates washout of the chamber. *a*, Recordings from the same ring before and after rubbing of its intimal surface. After the record on the left had been obtained, the ring was removed from the chamber on its mounting hooks. While it was kept under tension and moist with Krebs solution, its intimal surface was gently rubbed for 1 min with a small, wooden applicator stick that had been shaved down to permit easy insertion through the lumen. The ring was then resuspended in the muscle chamber and retested about 30 min later. A matched ring that was rubbed for the same time on its adventitial surface exhibited no loss of its capacity for relaxation by ACh (not shown). *b*, Simultaneous recordings from an unrubbed (left) and rubbed (right) transverse strip from the same aorta. Before being placed in clips for mounting, the latter strip had been dragged slowly for 1 min with intimal surface down, over a sheet of filter paper wetted with Krebs solution. A third strip, that had been similarly dragged with adventitial surface down, exhibited no loss of relaxation capacity (not shown). *c*, Simultaneous recordings from rings made from the same aorta before and after exposure of the intimal surface to a solution of collagenase, similar to that used by Jaffe *et al.*<sup>9</sup>, and containing 0.2% of the CLS-type enzyme preparation (Worthington) in a phosphate-buffered saline solution (PBS). The control ring (left) was cut first and incubated for 25 min in PBS alone at 37 °C. The remaining segment of aorta was cannulated at its upper end and closed with a clip at its lower end. It was then filled with collagenase solution and immediately immersed in PBS at 37 °C. After the desired exposure time, a ring was cut from near the lower end of the segment. The record on the right is for a ring whose intimal surface had been exposed to the collagenase solution at 37 °C for 15 min. Similar results were obtained in three other experiments. Rings whose intimal surfaces had been exposed for only 7 min showed about a 50% reduction in maximal relaxing response to ACh (not shown). A 15-min exposure to collagenase did not interfere with contraction elicited by high concentrations of ACh nor with relaxation by other agents such as isoprenaline, sodium nitrate and 5'-AMP.

**Fig. 2** Photomicrographs of the intimal surface of aortic preparations after various treatments. A preparation, cut open in strip form, was laid adventitia-side down on a small piece of paper towel, to which it adhered well during exposure to each solution in the silver staining procedure. The procedure was that of Poole *et al.*<sup>8</sup>, with the modification that the blood vessel preparation moved about in each solution for the recommended time, while on the paper-towel backing. After final fixation in 5% formalin, the preparation could be examined microscopically *en face* in the wet state, or it could be dehydrated and imbedded in a permanent mount. The photomicrographs here are of preparations after imbedding. Magnification is  $\times 218$ . *a*, Strip that was stained immediately after being cut from freshly excised and trimmed aorta. Almost all the intimal surface was covered by endothelial cells. *b*, Strip made from an unrubbed ring at the end of an experiment on drug testing. During the experiment ACh at  $10^{-6}$  M relaxed moderate NA-induced tone in this ring by about 95%. Only about 70% of the intimal surface (excluding those parts that had been apposed to the surface of the metal mounting hooks) was covered by endothelial cells. It was rare to find more than 80% retention of endothelial cells in unrubbed preparations examined at the end of an experiment. *c*, Strip that had had its intimal surface rubbed on filter paper for 1 min before being used in an experiment in which it gave no relaxation in response to ACh (similar to Fig. 1*b*). The surface was devoid of endothelial cells. *d*, Strip made from a ring from a segment of aorta that had been exposed intraluminally to 0.2% collagenase for 15 min at 37 °C. During the experiment the ring gave no relaxation in response to ACh (similar to Fig. 1*c*). No endothelial cells were left on the intimal surface.

**Fig. 3** Demonstration of release of a relaxing substance (or substances) from endothelial cells by ACh. Rings of uniform width (2.5 mm) were cut from a segment of descending thoracic aorta, and then cut across to yield transverse strips. Before the strips were mounted in muscle chambers, the intimal surfaces of three of them were rubbed on filter paper (as in Fig. 2b) to remove their endothelial cells. A second segment of aorta was incubated without tension in Krebs solution at 37 °C, and from it longitudinal strips (strips running parallel to the long axis) were cut as needed in the same dimensions as the transverse strips. Initially, all strips mounted for recording were mounted singly with plastic clips. Later, certain pairs of strips were mounted together in sandwich form, with their entire intimal surfaces apposed. *a*, NA and ACh on a transverse strip with endothelium removed. ACh did not relax NA-induced tone, and evoked additional contraction at  $1 \mu\text{M}$ . *b*, NA and ACh on a longitudinal strip with endothelium present. Only trivial changes in tension were exerted on the transducer (because of the orientation of the smooth muscle cells). *c*, NA and ACh on a sandwich made from the transverse strip without endothelium (same strip as in *a*) and a longitudinal strip with endothelium. The latter strip was cut from the incubated but unmounted segment of aorta in a region adjacent to that from which the strip that gave record *b* was cut. The sandwich was allowed to equilibrate for about 30 min after mounting. Note the relaxation at  $10^{-7}$  and  $10^{-6}$  M ACh. This was relaxation of the transverse strip, as it was this strip in the sandwich that gave the recorded tension increase on addition of NA. *d*, Test of NA and ACh on the transverse strip without endothelium after removing the longitudinal strip with endothelium. As in *a*, it now again gave no relaxation in response to ACh. In this experiment relaxation by ACh was also demonstrated in a second transverse strip without endothelium only when it was mounted in a sandwich preparation with a longitudinal strip with endothelium. However, in a sandwich preparation made with a longitudinal strip that had also been freed of endothelium (by rubbing) and a transverse strip without endothelium, the latter failed to relax in response to ACh. The results in this experiment were replicated in four similar experiments.

also studied in which endothelial cells had been removed by exposing the intimal surface to commercial collagenase<sup>9</sup>. Figure 1c shows that a ring from a collagenase-treated segment failed to relax in response to ACh, and Fig. 2d shows that the intimal surface of such a ring was completely free of endothelial cells.

To explain the obligatory role of endothelial cells in the relaxation, it was postulated that ACh acting on a muscarinic receptor in these cells stimulates them to release a substance (or substances) which in turn acts on the smooth muscle cells in the media to activate relaxation. Direct evidence for this hypothesis

was obtained in experiments in which a regular transverse strip freed of endothelial cells was tested when mounted separately and also when mounted, intimal surface against intimal surface, with a longitudinal strip of the same width and length with endothelial cells present (Fig. 3). Because of the orientation of its muscle cells, the longitudinal strip could contribute only trivial increases in tension on the strain gauge during contraction. As shown in Fig. 3, ACh, which failed to relax contraction of the transverse strip mounted separately, gave good relaxation of contraction of the same strip when it was mounted as a 'sandwich' with the longitudinal strip.

Although we have not identified the released relaxing substance(s), we have ruled out bradykinin, prostacyclin, cyclic AMP and cyclic GMP (no relaxation or only slight relaxation of

**Fig. 4** Inhibition of the relaxing action of ACh by anoxia, ETYA and mepacrine (MEP). *a*, Response of an aortic ring to ACh under oxygen (upper record) and under anoxia (lower record). About 30 min before making the lower record, 95%  $\text{N}_2$ -5%  $\text{CO}_2$  was substituted for 95%  $\text{O}_2$ -5%  $\text{CO}_2$ , and was bubbled rapidly through the solution in the muscle chamber. To minimize the chance of significant traces of  $\text{O}_2$  from air getting into the solution, the top of the chamber was covered with a plastic cap containing only two small holes, one for passage of the thread to the transducer and the other for introduction of needles of Hamilton syringes in adding drugs. In this and three similar experiments, the relaxing response to ACh was completely lost under anoxia. It was completely restored on return of the preparation to  $\text{O}_2$  (not shown). *b*, Acute inhibition by ETYA of ACh-induced relaxation. The ETYA was added as a solution in ethanol in a volume of  $60 \mu\text{l}$  to the 20 ml of Krebs solution in the muscle chamber. The addition of  $60 \mu\text{l}$  of ethanol alone in control experiments gave only small variable increases in tone (not shown). The ETYA concentration of  $10^{-4}$  M represents the concentration that would have been obtained if all ETYA had stayed in solution in the muscle chamber; however, some always came out of solution. The fall in tone that began about 2 min after the addition of ETYA and before washout (W) is the result of a marked (but reversible) depression of responsiveness to contractile agents that develops in aortic preparations on exposure to ETYA. *c*, Acute inhibition by mepacrine of ACh-induced relaxation. Mepacrine inhibition was readily reversed by washout.

aortic preparations), and also adenosine and 5'-AMP (maximal relaxation much less than with ACh in some experiments). In addition to prostacyclin, other products of cyclo-oxygenase activity were ruled out because inhibitors of that enzyme, indomethacin (40  $\mu$ M) and aspirin (100  $\mu$ M), had no effect on the relaxing action of ACh.

When aortic preparations were made anoxic, ACh produced very little or no relaxation (Fig. 4a). In the same conditions, agents like sodium nitrite, glyceryl trinitrate and isoprenaline still produced good relaxation. Inhibition of ACh-induced relaxation by anoxia has been reported previously for rings of dog femoral artery<sup>10</sup>. Furthermore, when 5, 8, 11, 14-eicosatetraenoic acid (ETYA) was added in sufficient concentration, it rapidly (<1 min) and often completely antagonized an ACh-induced relaxation (Fig. 4b). Moreover, exposure of preparations to 100  $\mu$ M ETYA for 30–60 min completely and irreversibly inhibited relaxation by ACh. Mepacrine at 20  $\mu$ M almost completely inhibited relaxation by ACh, whether it was added before or after the ACh. As ETYA is an inhibitor of lipoxygenase and cyclo-oxygenase<sup>11</sup> and as mepacrine inhibits the release of arachidonic acid from certain phosphatides (possibly by inhibiting phospholipase A<sub>2</sub> (ref. 12), these results suggest that ACh acting on the muscarinic receptor of the endothelial cells somehow activates a reaction sequence in which arachidonic (or some other unsaturated fatty acid) is liberated and then oxidized by lipoxygenase to a product that is responsible for the relaxation of the smooth muscle cells. The involvement of lipoxygenase is attractive despite negative results with the lipoxygenase inhibitor BW755C (ref. 13).

In experiments on other arteries, we have found that rings from the following exhibit ACh-induced relaxation before, but not after, rubbing of the intimal surface: rabbit superior mesenteric, pulmonary and ear arteries; rat thoracic aorta; guinea pig thoracic aorta, cat thoracic and abdominal aortae, superior mesenteric, pulmonary and external iliac arteries, dog circumflex and left anterior descending coronary arteries.

In relating the present *in vitro* findings to the vasodilating effect of ACh *in vivo*, it should be remembered that vasoconstriction of isolated blood vessels produced by stimulation of adrenergic nerves can be antagonized by ACh acting on pre-junctional muscarinic receptors of the nerve terminals<sup>14–17</sup>. As this antagonism depends on inhibition of the stimulation-evoked release of the adrenergic neurotransmitter NA<sup>16–18</sup>, it is a mechanism for vasodilatation by ACh only in blood vessels that are vasoconstricted by nerve stimulation. The endothelium-requiring mechanism explored here would be effective whether or not the vasoconstriction was caused by nerve stimulation. We propose that this mechanism applies in the case of smaller resistance vessels as well as for the larger arteries used in this study, and that it is one of the principal mechanisms responsible for the very potent vasodilating effect of ACh and other muscarinic agonists in intact animals.

We thank David Davidson and Peter Cherry for technical assistance, and Dr S. Moncada for supplying BW755C. The work was supported by USPHS grant NL 21860.

**Gastrin-cholecystokinin (CCK)-like immunoreactivity has been visualized by immunohistochemistry in the vasopressin-oxytocin neurosecretory system comprising the posterior lobe of the pituitary, the supraoptic and paraventricular nuclei of the hypothalamus<sup>1</sup>. This CCK-like substance has not been chemically identified in the rat, but has been reported to be gastrin 17 in the swine pituitary<sup>2</sup>. We report here that this CCK-like immunoreactive substance co-chromatographs with CCK8 sulphate on Sephadex G-50 and two HPLC chromatographic systems. No gastrin 17 was detected in rat pituitary or brain. We further report that about 60% of the CCK in posterior lobe originates in cell bodies in the paraventricular nucleus of the hypothalamus. The CCK content of posterior pituitary is dramatically decreased by physiological perturbations which stimulate vasopressin or oxytocin release. We propose that CCK may either be co-secreted with vasopressin and oxytocin to act on peripheral targets or may be involved in the regulation of vasopressin or oxytocin neurosecretion.**

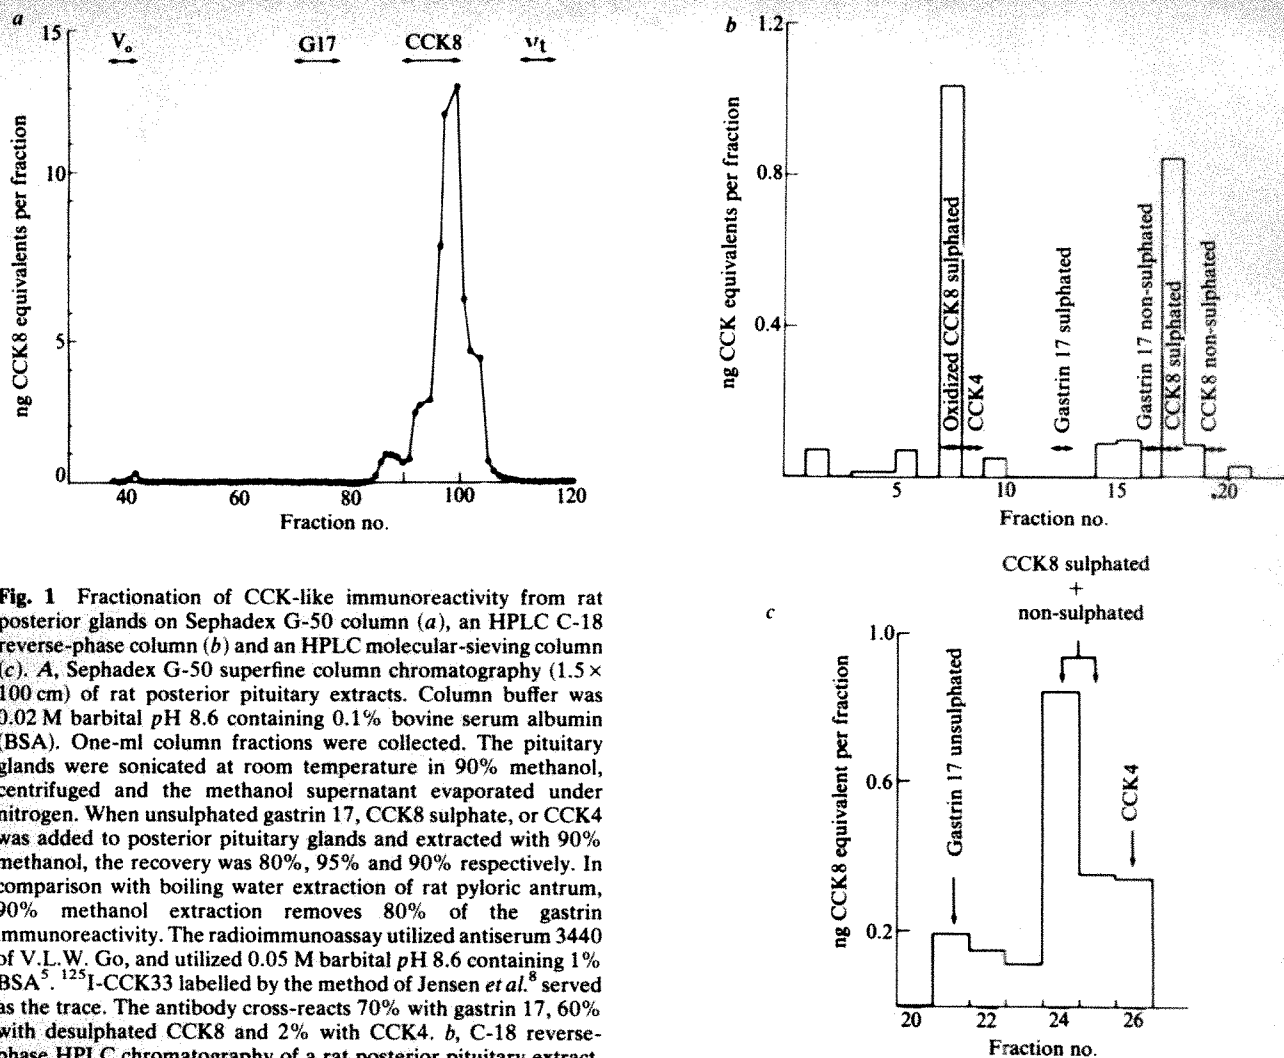

The CCK-like substance extracted with 90% methanol from rat posterior pituitary glands was fractionated on three chromatographic columns which separate CCK8 from gastrin: a Sephadex G-50 column, a HPLC reverse-phase C-18 column, and a HPLC molecular-sieving column. The pattern of elution of pituitary CCK immunoreactive material from these chromatographic columns was measured with a radioimmunoassay (RIA) which displayed 70% cross-reactivity with gastrin.

When a rat posterior pituitary extract was chromatographed on Sephadex G-50 the immunoreactivity emerged in one peak that had the same elution volume as synthetic sulphated CCK8 (Fig. 1a). Sephadex chromatography coupled with RIA has been used in the past to separate the molecular forms of CCK in central and peripheral nerves<sup>3</sup> and was, therefore, the first method applied in this study. However, as HPLC offers better

**Table 1** CCK content of posterior lobe in control and paraventricular lesioned rats

|                                      | CCK<br>(pg per lobe) |
|--------------------------------------|----------------------|
| Control (6)                          | 219 ± 46             |
| Paraventricular (6) nucleus lesioned | 89 ± 40              |

Bilateral paraventricular nucleus lesions were made under ether anaesthesia. Animals were placed in a Kopf stereotaxic device, 5° nose down. The electrode tips were positioned 6.4 mm rostral to the interauricular line, 0.4 mm lateral to the midline, 7.5 mm ventral to the dural surface. A current of 3 mA was passed through each electrode for 30 s. The lesions destroyed both paraventricular nuclei and damaged adjacent structures (anterior hypothalamic nuclei, ventral thalamus, perifornical area) to varying degrees. One week after the paraventricular nucleus lesions, the posterior lobe CCK content of lesioned Osborne-Mendel female rats and age-matched controls was determined. Note that strain differences exist in posterior pituitary CCK levels. Zivic-Miller rats have higher levels than Osborne-Mendel animals. Values are given as mean ± s.e.m.

**Fig. 1** Fractionation of CCK-like immunoreactivity from rat posterior glands on Sephadex G-50 column (a), an HPLC C-18 reverse-phase column (b) and an HPLC molecular-sieving column (c). **A**, Sephadex G-50 superfine column chromatography ( $1.5 \times 100$  cm) of rat posterior pituitary extracts. Column buffer was 0.02 M barbital pH 8.6 containing 0.1% bovine serum albumin (BSA). One-ml column fractions were collected. The pituitary glands were sonicated at room temperature in 90% methanol, centrifuged and the methanol supernatant evaporated under nitrogen. When unsulphated gastrin 17, CCK8 sulphate, or CCK4 was added to posterior pituitary glands and extracted with 90% methanol, the recovery was 80%, 95% and 90% respectively. In comparison with boiling water extraction of rat pyloric antrum, 90% methanol extraction removes 80% of the gastrin immunoreactivity. The radioimmunoassay utilized antiserum 3440 of V.L.W. Go, and utilized 0.05 M barbital pH 8.6 containing 1% BSA<sup>5</sup>.  $^{125}$ I-CCK33 labelled by the method of Jensen *et al.*<sup>8</sup> served as the trace. The antibody cross-reacts 70% with gastrin 17, 60% with desulphated CCK8 and 2% with CCK4. **b**, C-18 reverse-phase HPLC chromatography of a rat posterior pituitary extract. Chromatography was through a Supelco LC-18 HPLC column<sup>9</sup>. Elution buffer was 22% acetonitrile-78% triethylamine-phosphoric acid buffer pH 6.5. The position of partially and completely oxidized CCK and gastrin was determined by deliberately oxidizing the peptide with hydrogen peroxide and following the time course of the oxidation with the HPLC. **c**, Varian 2000 molecular-sieving HPLC column chromatography<sup>9</sup> of a rat posterior pituitary extract. Elution buffer was phosphate-buffered saline (PBS) pH 6.5. Before radioimmunoassay the fractions were passed through and eluted from a Waters C-18 Sep-pack to remove the PBS.

resolution of CCK peptides than Sephadex, two HPLC systems were also utilized to chromatograph rat posterior pituitary extracts.

In Fig. 1b the elution of a rat posterior pituitary extract from a HPLC reverse-phase C18 column is shown. All of the immunoreactivity emerges in two column fractions, one of which coincides with partially oxidized sulphated CCK8 and the other with reduced (that is, native) sulphated CCK8. No immunoreactivity co-migrates with sulphated or unsulphated gastrin 17 (in either their native or oxidized forms) or with CCK4 (Trp-Met-Asp-Phe-NH<sub>2</sub>). However, although 90% methanol can efficiently extract CCK4, the cross-reactivity of the antibody with CCK4 is sufficiently low that the existence of some CCK4 cannot be excluded.

In Fig. 1c the elution pattern of a rat pituitary extract from an HPLC molecular-sieving column is shown. The bulk of the immunoreactivity elutes with sulphated and desulphated CCK8; little material elutes with gastrin 17. Thus, sulphated CCK8 is the dominant CCK-like immunoreactive substance in the posterior pituitary of the rat, as it is in rat brain<sup>3-5</sup>. The presence of large amounts of gastrin 17 in the pig pituitary<sup>2</sup> may reflect species differences.

The distribution of CCK in the hypothalamus and pituitary resembles the distributions of vasopressin and oxytocin. As mentioned above, CCK-containing cell bodies have been visualized in the supraoptic and paraventricular nuclei by means of immunocytochemistry, and a dense collection of CCK fibres is

found in the median eminence and posterior pituitary<sup>1,6</sup>. Considerable CCK was detected by RIA in Osborne-Mendel female rats in paraventricular and supraoptic nuclei ( $0.86 \pm 0.1$  and  $1.5 \pm 0.4$  ng CCK8 equivalents per mg protein ( $n = 3$ ), respectively), more CCK in median eminence ( $2.3 \pm 0.5$  ng per mg protein) and still more in posterior pituitary ( $4.4 \pm 1.3$  ng per mg protein or 200–300 pg per lobe). CCK was undetectable ( $<10.0$  pg per pituitary) in the intermediate and anterior lobes of the pituitary.

To determine whether the CCK in the posterior pituitary is intrinsic to it, the CCK content was measured in pituitaries of stalk sectioned Zivic-Miller rats. One week after the stalk sections were performed the CCK content of the posterior pituitaries was undetectable. This indicates that all of the CCK in the posterior pituitary has an extrapituitary origin. The paraventricular nucleus contributes a substantial portion of the posterior lobe's CCK as paraventricular nucleus lesions reduced the CCK content of the posterior pituitary by 60% (Table 1).

To determine whether CCK might be secreted in parallel with vasopressin and/or oxytocin, the posterior pituitary CCK content was determined in lactating rats and rats given 2% saline to drink. The results are shown in Table 2. In lactating animals whose oxytocin release is increased, the CCK content in the posterior pituitary was reduced to 17% of control. In rats given 2% saline to drink for 5 days, a treatment which is known to reduce vasopressin by 80% (ref. 7), the pituitary CCK content was about 20% of control.

**Table 2** CCK in posterior lobe in lactating and salt-treated rats

|                  | CCK<br>(pg per lobe) |
|------------------|----------------------|
| Controls (9)     | 257 ± 36             |
| Salt treated (6) | 56 ± 20              |
| Lactating (3)    | 43 ± 4               |

Osborne-Mendel female rats (250 g) which were given 2% NaCl for 5 days were compared with controls given tap water. Lactating Osborne-Mendel rats were separated from their pups and compared with age-matched female controls. The CCK concentrations of both control groups were the same so the data were pooled. Numbers in parentheses refer to the number of animals tested. This experiment was repeated once with similar results. Values are mean ± s.e.m.

The CCK content of posterior pituitary is thus dramatically decreased by physiological perturbations which stimulate the release of vasopressin and oxytocin. We propose that CCK may either be co-secreted with vasopressin and oxytocin to act on peripheral targets, or may be involved at the pituitary level in the regulation of vasopressin or oxytocin secretion. Whether CCK is found in the same or different neurones as vasopressin or oxytocin remains to be determined.

## VIP as a possible neurotransmitter of non-cholinergic non-adrenergic inhibitory neurones

Many peripheral autonomic nerves are neither cholinergic nor adrenergic. Such nerves are widely distributed in the gastrointestinal, urogenital and respiratory tracts, and in blood vessels<sup>1,2</sup>. The nature of their neurotransmitter is not known. We have previously reported that vasoactive intestinal polypeptide (VIP) is a potent inhibitor of opossum lower oesophageal sphincter (LOS) and that its inhibitory effect is exerted directly on the sphincter muscle<sup>3</sup>. Subsequent studies have confirmed the inhibitory effect of VIP on LOS in other species<sup>4-6</sup>. Recently, very high tissue levels of VIP have been reported in the LOS and other gastrointestinal sphincters<sup>7</sup>. Furthermore, VIP has been localized to intramural neurones and is released upon electrical stimulation of the vagus nerve<sup>8,9</sup>. We report here that immunoantagonism of VIP with a high-titre antiserum antagonized inhibitory neuromuscular transmission in the LOS. These findings provide evidence of a role for VIP as an inhibitory neurotransmitter.

\* To whom correspondence should be addressed.

Experiments were performed in opossums (*Didelphis virginiana*) anaesthetized with pentobarbital (40 mg per kg). Opossum LOS is suitable for these studies because it maintains a resting tone independent of tonic neural activity and the vagus nerves carry predominantly inhibitory influences to the LOS<sup>10</sup>. Moreover, the inhibitory neurones that lie in the vagal pathway have been shown to be non-cholinergic and non-adrenergic in nature<sup>11</sup>.

The lower oesophageal sphincter pressures (LOSP) were monitored with water-filled, continuously perfused catheters that were anchored in the LOS as described elsewhere<sup>12</sup>. Ringer's solution, control serum (non-immune serum from an unimmunized rabbit), VIP antiserum or VIP antiserum preabsorbed *in vitro* with native VIP, were infused into the branch of left gastric artery that supplies the sphincter<sup>13</sup>. VIP antiserum no. 89N was raised in a rabbit immunized with a conjugate of natural porcine VIP and bovine serum albumin. Using the antiserum in a dilution of 1:300,000 at 4°C, the equilibrium constants of association were found to be  $K_{a1} = 6.7 \times 10^{10} \text{ M}^{-1}$  and  $K_{a2} = 2.3 \times 10^9 \text{ M}^{-1}$ . The binding capacity of the undiluted antiserum was calculated to be 57 µg VIP per ml of antiserum. *In vitro* assay showed no cross-reactivity with gastric inhibitory polypeptide, glucagon, secretin, substance P, porcine pancreatic polypeptide, cholecystokinin or gastrin. The antiserum from the same batch was neutralized by addition of VIP (57 µg VIP per ml of antiserum). The mixture was kept overnight and then centrifuged to remove any precipitate before its use.

The brachial vein was used for intravenous (i.v.) administration of VIP. Vagal efferent stimulation was provided by electrical stimulation of the peripheral end of the cut vagus nerve in the neck<sup>10</sup>. Stimulation of intramural neurones was achieved with electrodes inserted into the wall of the sphincter as described elsewhere<sup>12</sup>. Nicotine (40 µg per kg) was administered intravenously<sup>14</sup>.

**Fig. 1** The influence of intra-arterial VIP antiserum on the inhibitory effect of intravenously administered VIP on the LOSP. The corresponding Ringer controls for control serum (○, 1:12.5) and VIP antiserum (●, 1:12.5) are represented by △ and ▲ respectively. VIP antiserum significantly (\*) antagonized the effect of all doses of VIP studied. This antagonism was significant ( $P < 0.05$ ) when compared to either control serum or the Ringer's infusion. Each point is mean ± s.e. of four observations.

Two separate groups, each of four animals, were studied. One group received an infusion of Ringer's solution followed by control serum. The second group received Ringer's solution followed by VIP antiserum. All infusions were made at the rate of 5 ml h<sup>-1</sup>. The pressure recording was coded and results were analysed blindly. Intravenous administration of VIP produced a dose-dependent fall in LOSP, which was not modified by control serum (1:12.5 dilution). In contrast, VIP antiserum (1:12.5) significantly ( $P < 0.05$ ) antagonized the inhibitory effect of VIP at all dose levels (Fig. 1). Thus the antiserum was effective in partially antagonizing the effect of exogenous VIP. Higher dilutions of antiserum 1:50 were ineffective and the dilution of 1:25 produced inconsistent effects.

Electrical stimulation of vagal efferents produced a frequency-dependent fall in the sphincter pressure. Other

parameters of stimulation were 10 V, 0.5 ms square pulses for 2-s train duration. Infusion of control serum did not modify vagal-stimulated sphincter relaxation at any of the frequencies of stimulation examined ( $P > 0.05$ , Fig. 2).

**Fig. 2** The influence of VIP antiserum on the vagal-stimulated fall in LOSP. Note that vagal stimulation produced frequency-dependent fall in LOSP. VIP antiserum significantly (\*) antagonized the inhibitory effect of vagal stimulation at all the frequency levels studied ( $P < 0.05$ ). Control serum did not modify the effect of vagal stimulation. The corresponding Ringer controls in two different groups for control (○) and VIP antiserum (●) are represented by △ and ▲ respectively. Each point is mean  $\pm$  s.e. of 9–12 observations. p.p.s., Pulses per s.

As the vagal pathway to the LOS muscle consists of pre-ganglionic fibres that synapse with postganglionic inhibitory neurones<sup>11</sup>, the effect of VIP antiserum on vagal-stimulated sphincter relaxation could be exerted at the preganglionic or at the postganglionic level. To examine these alternatives we investigated the effect of postganglionic neuronal activation with intramural electrical stimulation. We have previously shown that intramural stimulation in this preparation activates postganglionic neurones as the effect of such a stimulation is not antagonized by synaptic block with a combination of hexamethonium and atrophine<sup>15</sup>. Effect of ganglionic stimulant nicotine<sup>14</sup> was also examined.

LOS relaxation induced by intramural stimulation was significantly antagonized by VIP antiserum but was unaffected by control serum (Fig. 3). Likewise, the fall in LOSP induced by nicotine was antagonized by VIP antiserum but not by control serum. Nicotine (40  $\mu$ g per kg) caused  $83.4 \pm 3.2$  (s.e.) per cent fall in LOSP during control serum and  $58.7 \pm 5.9$  per cent during VIP antiserum infusion ( $P < 0.05$ ,  $n = 5$ ). These results suggest that the VIP antiserum acted at the postganglionic neuromuscular site.

The effect of VIP antiserum on all the stimuli studied above could theoretically be due to its non-selective action on the LOS

smooth muscle. To examine this, we studied the effect of a direct-acting inhibitory agent, isoproterenol. VIP antiserum did not modify its inhibitory action. Isoproterenol (2.5  $\mu$ g per kg) caused  $84.7 \pm 3.1$  per cent fall in LOSP during the infusion of control serum and  $85.0 \pm 2.6$  per cent during the VIP antiserum infusion ( $P > 0.05$ ,  $n = 5$ ).

The control serum used in these studies was not obtained from the same animal that provided the VIP antiserum. Theoretically the observed influence of the VIP antiserum could have been due to an unknown inhibitor other than the VIP antibody. To test this, we examined the influence of VIP antiserum that was preabsorbed with VIP before administration. As summarized in Table 1, preabsorbed VIP antiserum did not modify the effects of exogenous VIP, vagal or transmural stimulation in the same animal. These observations support the view that the inhibitory effect of VIP antiserum was due to the VIP antibody.

These immunopharmacological studies provide evidence for the role of VIP as a neurotransmitter of the inhibitory neurones in the LOS. This conclusion is supported by immunohistochemical demonstration of VIP in the intramural neurones and its release upon electrical stimulation of vagus nerves<sup>9,16–19</sup>.

**Fig. 3** Influence of VIP antiserum on the effect of intramural stimulation on LOSP. Note that VIP antiserum significantly (\*) antagonized the inhibitory effect of intramural stimulation ( $P < 0.05$ ). Control serum, however, failed to modify the effect of intramural stimulation. Each point is mean  $\pm$  s.e. of 12 observations.

The VIP antiserum in the dilution of 1:12.5 did not fully antagonize the effect of exogenous VIP or of inhibitory neurone stimulation. This may be because the large size of the antibody makes it difficult for the antibody molecule to achieve sufficiently high concentrations in the extracellular space at the site of neuromuscular transmission. Moreover, the time course and the affinity of binding of the released VIP with the antiserum compared to that with the muscle receptors may also influence the degree of the antagonism. Higher concentration of antiserum could further antagonize the inhibitory response to exogenous or neurally-released VIP. Further studies are needed to resolve these issues. Alternatively, VIP may be only one of two or more neurotransmitters that are released by non-adrenergic, non-cholinergic inhibitory neurones<sup>20</sup>. Burnstock originally suggested that ATP or a related nucleotide is the neurotransmitter of the non-cholinergic, non-adrenergic neurones, which he termed 'purinergic' neurones<sup>1</sup>. Recent studies, however, do not support the view of purinergic nature of the inhibitory neurotransmitter in the opossum LOS<sup>21</sup>.

## Peptidergic transmitters in synaptic boutons of sympathetic ganglia

L. Y. Jan, Y. N. Jan & M. S. Brownfield

Department of Physiology, University of California, School of Medicine, San Francisco, California 94143

In sympathetic ganglia of the bullfrog, a slow synaptic potential lasting for minutes—the late slow excitatory postsynaptic potential (e.p.s.p.)—was discovered<sup>1</sup>. This slow response, unlike other previously known synaptic potentials in the autonomic nervous system, is not mediated by acetylcholine or monoamines. Similar non-cholinergic, non-adrenergic slow synaptic potentials have since been found in several other vertebrate autonomic ganglia<sup>2</sup>. We found that the late slow e.p.s.p. is probably mediated by a peptide that is identical to, or closely resembles, mammalian luteinizing hormone releasing hormone (LHRH)<sup>3</sup>, because (1) when applied directly to sympathetic neurones, LHRH and its agonists elicit a slow depolarization, associated with similar changes in membrane conductance and excitability as those occurring during the late slow e.p.s.p. Furthermore, both peptide-induced and nerve-evoked responses are blocked by antagonists of LHRH; and (2) radioimmunoassays indicate that a chain of sympathetic ganglia contains 100–800 pg of a LHRH-like peptide. Its distribution among spinal nerves, the great reduction of this substance following denervation, and its release from ganglia following isotonic KCl treatment or nerve stimulation suggest that the LHRH-like material is contained in preganglionic nerve fibres. Here we report that immunohistochemical staining of sympathetic ganglia shows that LHRH-like immunoreactivity is indeed present in synaptic boutons. We also show that the two types of ganglion cells (B cells and C cells) receive strikingly different patterns of peptidergic innervation.

The ninth and tenth ganglia of the bullfrog, the two most caudal ones in the paravertebral sympathetic chain, were used in these experiments because extensive electrophysiological studies have used them. By using several anti-LHRH sera raised in different laboratories, and the peroxidase–antiperoxidase (PAP) technique of Sternberger and co-workers<sup>4</sup>, we stained many boutons on the ganglion cell soma, particularly around the axon hillock region (Fig. 1a). To ensure that the staining was specific for LHRH-like immunoreactivity, we used the same anti-LHRH sera preadsorbed with LHRH in control experiments. Figure 1b shows that preadsorption completely abolishes the staining. Thus, the immunohistochemical procedure shows that the LHRH-like immunoreactivity is confined to synaptic boutons in sympathetic ganglia.

**Fig. 1** Vibratome-sectioned sympathetic ganglia treated with *a*, anti-LHRH sera, or *b*, same anti-LHRH sera preadsorbed with excess synthetic LHRH ( $40 \mu\text{g ml}^{-1}$ ), according to the PAP procedure of Sternberger<sup>4</sup>. In *c*, the seventh and eighth rami had been cut 5 days before the ganglia were stained with anti-LHRH sera (arrow indicates residual staining). In all cases, bullfrogs were anaesthetized with ethyl *m*-aminobenzoate and perfused through the ventricle with 4% paraformaldehyde, 0.1% glutaraldehyde in 0.15 M phosphate buffer at pH 7.4. The sympathetic chains were removed, postfixed in the same fixative for 30 min, and cut into 50- $\mu\text{m}$  sections on a vibratome. Rabbit antisera to LHRH were diluted 1:1,000 with 0.05 M Tris-buffered saline, pH 7.6, containing 1 mg  $\text{ml}^{-1}$  bovine serum albumin, 1% normal sheep serum, and 0.4% Triton X-100 and used to treat sections of ganglia for 24 h at 4°C. This incubation with primary rabbit antisera was followed sequentially by an incubation with sheep antisera specific for rabbit gamma immunoglobulins (IgG) and an incubation with rabbit PAP complex. Sheep antisera against rabbit IgG and rabbit PAP were used at 1:20 dilution in Tris-buffered saline containing 1% normal sheep serum and 0.02% Triton X-100. In each case, the incubation lasted 1 h at room temperature. Between incubations, vibratome sections were first washed for 2 h or longer in the same solution as that used in diluting the antisera for the previous incubation and then treated for 30 min with 5% normal sheep serum in the same solution as that used in diluting the antisera for the following incubation. *d*, HRP-filled terminals in partially denervated sympathetic ganglia. The sympathetic chain was severed above the seventh ganglion 5 days before preganglionic fibres were filled orthodromically with HRP. This denervation procedure removes cholinergic terminals around B cells, but leaves intact cholinergic terminals on C cells and peptidergic terminals for the late slow e.p.s.p. Note that very few terminals are found near B cells. To fill preganglionic fibres, a fresh cut was made in the chain below the seventh ganglion and the cut end was taken up in a suction electrode containing 30% HRP and 3% lysocleithin in  $\text{dH}_2\text{O}$ . Sixteen h later, the ganglia were fixed with 2% glutaraldehyde in 0.1 M phosphate buffer, pH 7.4, for 1 h, cut into 50- $\mu\text{m}$  sections on a vibratome, and reacted in a mixture of 0.5 mg  $\text{ml}^{-1}$  DAB and 0.0009%  $\text{H}_2\text{O}_2$  in 0.1 M phosphate-buffered saline for 10–15 min. B and C in *a*, *d* indicate B cells and C cells respectively, as judged from their sizes. In all cases, the sections were unstained, apart from the end-product of the peroxidase reactions.

**Table 1** Distribution of LHRH-positive boutons in sympathetic ganglia

|                         | Small cells<br>( $<28\ \mu\text{m}$ in diameter) |           |           | Medium cells<br>( $>28\ \mu\text{m}$ , $<42\ \mu\text{m}$ in diameter) |           |           | Large cells<br>( $>42\ \mu\text{m}$ in diameter) |           |           |
|-------------------------|--|-----------|-----------|--|-----------|-----------|--|-----------|-----------|
|                         | No. stained                                      | Total no. | % Stained | No. stained  | Total no. | % Stained | No. stained                                      | Total no. | % Stained |
| Normal                  | 640  | 792       | 81        | 307  | 653       | 47        | 14   | 203       | 7         |
| Unilaterally denervated | 84   | 451       | 19        | 164  | 557       | 29        | 177  | 356       | 50        |
| Bilaterally denervated  | 13   | 502       | 2.6       | 85   | 508       | 17        | 55   | 203       | 27        |

50- $\mu\text{m}$  thick sections of ganglia stained immunohistochemically with PAP and Sternberger's antisera for mammalian LHRH (see Fig. 1 legend) were examined with a Zeiss microscope and a  $\times 40$  water immersion lens. Diameters of cells surrounded with LHRH-positive boutons were measured, as were diameters of cells which clearly had no staining in their vicinity. (Using such criteria, the latter cell type is probably somewhat under-represented.) 'Diameters' for oblong cells were estimated as the geometric mean of the length and width of each cell. No corrections were made on account of the thickness of the sections. 'No. stained', number of cells surrounded by LHRH-positive terminals; 'Total no.', the sum of the number of cells surrounded by LHRH-positive terminals and the number of cells clearly void of stained terminals in their vicinity; '% Stained', the ratio of no. stained to total no. 'Normal' includes sections of ninth and tenth ganglia from five frogs; 'Unilaterally denervated' includes sections of ninth and tenth ganglia with their ipsilateral input from the seventh and eighth spinal nerves removed for 10 days (three frogs); and 'Bilaterally denervated' includes sections of ninth and tenth ganglia from two frogs whose seventh and eighth rami on both sides had been cut for 10 days.

The principal neurones in the ninth and tenth ganglia can be divided into two groups<sup>5</sup>: B cells and C cells. B cells are larger (with diameters from  $\sim 30$  to  $\sim 70\ \mu\text{m}$ ). They send out axons that conduct at velocities of about  $2\ \text{m s}^{-1}$ . C neurones are smaller (with diameters from  $\sim 20$  to  $\sim 45\ \mu\text{m}$ ) and their axons conduct at speeds  $\sim 0.2\ \text{m s}^{-1}$ . Both B and C cells give late slow e.p.s.ps on stimulation of the seventh and eighth spinal nerves, which carry most of this non-cholinergic input. Cholinergic inputs to these cells, however, are segregated anatomically<sup>6</sup>. B cells are innervated by cholinergic fibres from the chain above the seventh ganglion whereas C cells receive cholinergic input through the seventh and eighth spinal nerves (Fig. 2).

Although physiological studies have shown that most B and C cells give late slow e.p.s.ps on stimulation of the seventh and eighth spinal nerves<sup>3,6</sup>, immunohistochemical experiments reveal that LHRH-positive synaptic boutons are mainly around C cells (14 frogs). Cell counts on 50- $\mu\text{m}$  thick sections of ganglia from five frogs showed that 640 out of 792 small cells (with diameters  $<28\ \mu\text{m}$ ) were surrounded by LHRH-positive synaptic boutons, whereas only 14 out of 203 large cells (with diameters  $>42\ \mu\text{m}$ ) were surrounded by LHRH-positive terminals (Table 1). As physiological studies have shown that almost all cells larger than  $45\ \mu\text{m}$  in diameter are B cells, whereas cells smaller than  $30\ \mu\text{m}$  in diameter are most likely C cells, it seems that most, if not all, LHRH-positive nerve terminals are apposed to C cells.

This preferential staining of synaptic boutons around C cells was confirmed with two different approaches. First, we eliminated the cholinergic input to B cells by cutting the sympathetic chain above the seventh ganglion, identified B cells which gave the late slow e.p.s.p. but no cholinergic synaptic potentials, and serial-sectioned through those cells to look for remaining terminals using an electron microscope. Of the three B cells studied, none had terminals directly apposed to its membrane. Second, we again cut the chain above the seventh ganglion to remove the cholinergic innervation to B cells, leaving intact the cholinergic innervation to C cells plus peptidergic inputs to both B and C cells (Fig. 2). Then we used horseradish peroxidase (HRP) to fill terminals of preganglionic fibres arising from the seventh and eighth spinal nerves. Again, HRP-filled terminals were found around C cells, but hardly any filled terminals were found on B cells (Fig. 1d). Together, these anatomical approaches suggest that synaptic boutons containing LHRH-like immunoreactivity are almost exclusively around C cells. The similarity between the pattern of distribution of LHRH-positive boutons and that of HRP-filled terminals around C cells raises the question of whether acetylcholine and LHRH might exist in the same synaptic boutons, as has been suggested in some systems<sup>7</sup>.

To test further whether these LHRH-positive boutons arise from preganglionic fibres responsible for the late slow e.p.s.p., we removed most of those fibres from the ganglia by cutting the

seventh and eighth rami (Fig. 2). Previous physiological and anatomical studies have shown that after the preganglionic fibres are cut, synaptic transmission fails and nerve terminals of cut axons degenerate in a few days, but the ganglion cells retain their membrane potentials and give impulses. As expected, immunohistochemical staining of denervated ganglia showed that the staining for LHRH-like immunoreactivity was

**Fig. 2** Scheme of innervation of principal cells in ninth or tenth ganglia, the last two ganglia in the sympathetic chain. B cells are larger ( $\sim 30$  to  $\sim 70\ \mu\text{m}$  in diameter), whereas C cells are generally smaller (with diameters from  $\sim 20$  to  $\sim 45\ \mu\text{m}$  possibly down to  $10$ – $15\ \mu\text{m}$ ). Cholinergic axons for B neurones reach these ganglia through the sympathetic chain above the seventh ganglion, whereas preganglionic fibres for C neurones come through the seventh and eighth spinal nerves. The majority of LHRH-positive preganglionic axons for all neurones in the ninth and tenth ganglia also enter through the seventh and eighth nerves. Peptidergic input to B neurones is represented by dotted lines, because very few LHRH-positive boutons are found near large B neurones. It is not yet known whether acetylcholine and the LHRH-like peptide exist in the same nerve terminals around C cells.

essentially normal in the ninth and tenth ganglia after the chain was severed above the seventh ganglion (three frogs). On the other hand, cutting the seventh and eighth rami greatly reduced the staining (Fig. 1c). Rather unexpectedly, the distribution of staining in these denervated ganglia turned out to be drastically different from the normal pattern. Most of the cells surrounded by LHRH-positive boutons are large B cells (Table 1). The residual staining around C cells may be accounted for by a small percentage of peptidergic input from the contralateral seventh and eighth spinal nerves, as from previous electrophysiological experiments we knew that such contralateral contributions normally exist and that they increase after the ipsilateral input is removed, possibly as a result of sprouting<sup>8</sup>. Indeed, in two frogs whose seventh and eighth rami were cut on both sides, only 2.6% of small cells were surrounded by LHRH-positive boutons (Table 1), compared with 19% in unilaterally denervated frogs or 81% in the unoperated frog. Therefore, cutting preganglionic fibres from the seventh and eighth rami almost completely removed staining around C cells. The staining around large cells after denervation could be due to sprouting of the remaining few LHRH-positive fibres, which occasionally arise from the ninth spinal nerve, uptake of LHRH-positive materials into cholinergic nerve terminals, or other factors. Further studies are necessary to answer this question.

LHRH-like immunoreactivity has been found in synaptic boutons, as seen by light microscopy, in sympathetic ganglia. Further, denervation experiments suggest that these LHRH-positive synaptic boutons are probably the preganglionic nerve terminals for the late slow e.p.s.p. This considerably strengthens our hypothesis that the transmitter for the late slow e.p.s.p. in frog sympathetic ganglia is a LHRH-like peptide. Although the late slow e.p.s.p. is present in both B and C cells, LHRH-positive synaptic boutons are mainly around C cells. Therefore, whereas C cells may receive peptidergic transmitters from synaptic boutons in the vicinity of their cell bodies, the late slow e.p.s.p.s. recorded in B cells must be largely due to diffusion of the LHRH-like peptides from terminals around C cells. The delayed and variable onset of the late slow e.p.s.p. recorded in different B cells is compatible with the suggestion that B cells receive peptidergic transmitters that are released at a distance. This result implies that inactivation of this peptidergic transmitter must be relatively slow. Indeed, if an antagonist of LHRH is ejected by pressure on to a B cell anytime during a late slow e.p.s.p., the slow synaptic potential is truncated right away<sup>8</sup>, suggesting that the slowness of this response is partly due to the prolonged presence of transmitters after they are released on nerve stimulation. The fact that sympathetic ganglia contained two anatomically distinct types of peptidergic innervation, together with their relative structural simplicity and easy access, makes them a promising model for detailed analysis of peptidergic transmission.

We thank Drs W. Vale and J. Rivier of the Salk Institute for peptides and rabbit antisera, Drs L. A. Sternberger and G. P. Kozlowski for rabbit antisera, and Louise Evans for photography. ## Do human platelets have opiate receptors?

A. Reches\*, A. Eldor†, Z. Vogel‡ & Y. Salomon§

In their study of prostaglandin E<sub>1</sub> (PGE<sub>1</sub>)-sensitive adenylate cyclase (AC) in rat brain homogenates, Collier and Roy<sup>1</sup> claimed that the activity of this enzyme is inhibited by opiates. They also proposed that opiates exert their analgesic and allied effects by inhibiting AC of neurones that are normally stimulated by E prostaglandins<sup>2</sup>. Studies using neuroblastoma × glioma hybrid cells<sup>3,4</sup> supported this hypothesis. However, subsequent studies with the mammalian brain<sup>5,6</sup> and rat brain tissue slices<sup>7,8</sup> yielded conflicting results. PGE<sub>1</sub> also inhibits platelet aggregation<sup>9</sup>, probably through activation of platelet AC<sup>10</sup>. Gryglewski *et al.*<sup>11</sup> showed that morphine inhibits the anti-aggregating effect of PGE<sub>1</sub> on ADP- and adrenaline-induced platelet aggregation, and suggested that the inhibition by morphine is mediated through platelet AC activity. We report here our attempts to reproduce the results of Gryglewski *et al.* and our examination of the effect of morphine on PGE<sub>1</sub>-sensitive AC activity in platelet lysates and on PGE<sub>1</sub>-induced accumulation of cyclic AMP in intact platelets. The possible existence of opiate receptors in platelets was also assessed by direct binding studies with <sup>3</sup>H-etorphine. In contrast to Gryglewski *et al.*<sup>11</sup>, we could not detect any effect of opiates on the aggregation of human platelets, nor did we find any other evidence supporting the presence of opiate receptors in these cells. Thus we conclude that the presence of opiate receptors in human platelets is unlikely.

Blood collection and preparation of citrated platelet-rich and platelet-poor plasmas were done according to Han and Ardlie<sup>12</sup>. Platelet aggregation was measured by the turbidometric technique of Born<sup>13</sup>, as described previously<sup>14</sup>. Human platelet lysates were prepared by a modification of the method of Jakobs *et al.*<sup>15</sup>, as described previously<sup>14</sup>. Homogenates of rat corpus striatum (10% w/v in 0.32 M sucrose 10 mM Tris-HCl pH 7.6) and P<sub>2</sub>-pellets were prepared according to Gray and Whittaker<sup>16</sup>.

Adenylate cyclase activity in platelet lysates was determined as described previously by measuring the conversion of [ $\alpha$ -<sup>32</sup>P]ATP (Amersham) to <sup>32</sup>P-cyclic AMP by the method of Salomon<sup>17</sup>. Cyclic AMP accumulation in intact <sup>3</sup>H-adenine (Negev)-prelabelled platelets was as described previously<sup>17</sup>.

Binding of  $^3\text{H}$ -etorphine (Amersham) to platelet lysates was measured as described for rat brain homogenates<sup>18</sup>. The amount of lysate protein was 0.05–0.45 mg per assay.  $^3\text{H}$ -etorphine concentration was 3.0 nM and incubations were performed in a final volume of 250  $\mu\text{l}$  for 30 min at 37 °C. The experiments were repeated 3–5 times with platelet preparations derived from several healthy volunteers who had not taken any drugs for at least 1 week before blood collection.

$\text{PGE}_1$ , 0.02–0.34  $\mu\text{M}$ , inhibited ADP-induced aggregation in a dose-dependent manner. In five experiments we used 0.14  $\mu\text{M}$   $\text{PGE}_1$  (the concentration used by Gryglewski *et al.*<sup>11</sup>). At this concentration  $\text{PGE}_1$  inhibited ADP-induced platelet aggregation by  $70.5\% \pm 1 \text{ s.e.m.}$  In these conditions we tested a wide range of morphine concentrations (13.2–53  $\mu\text{M}$ ). No significant effect on the anti-aggregating properties of  $\text{PGE}_1$  could be demonstrated.

Stimulation of platelet AC by  $\text{PGE}_1$  in the concentration range of 0.01–0.35  $\mu\text{M}$  was dose dependent. At the highest concentration (0.35  $\mu\text{M}$ ),  $\text{PGE}_1$  stimulated AC activity by about 6–20-fold (Table 1). We tested platelet preparations from four donors but could not demonstrate any inhibitory effect of morphine (13.3  $\mu\text{M}$ ) on basal (unstimulated) or  $\text{PGE}_1$ -sensitive AC activity (Table 1). The concentration of morphine selected for this experiment was that reported by Gryglewski *et al.*<sup>11</sup> to be optimal in their experiments.

**Table 2** The effect of  $\text{PGE}_1$  and morphine on the intracellular accumulation of  $^3\text{H}$ -cyclic AMP in intact platelets prelabelled with [ $2\text{-}^3\text{H}$ ]adenine

| Additions                            | Morphine ( $\mu\text{M}$ )        |              |              |
|--------------------------------------|-----------------------------------|--------------|--------------|
|                                      | 0                                 | 13.3         | 26           |
|                                      | $^3\text{H}$ -cyclic AMP (c.p.m.) |              |              |
| None                                 | $85 \pm 2$                        | $93 \pm 5$   | $98 \pm 2$   |
| $\text{PGE}_1$ (0.14 $\mu\text{M}$ ) | $496 \pm 25$                      | $525 \pm 19$ | $540 \pm 28$ |

Results are given in c.p.m., mean  $\pm$  s.d. ( $n = 4$ ).

To eliminate the possibility that the inhibitory effect of morphine may not be demonstrable at saturating  $\text{PGE}_1$  concentrations, we also tested its effect at submaximal concentrations of  $\text{PGE}_1$ . At 0.04  $\mu\text{M}$   $\text{PGE}_1$ , AC activity was stimulated over 65–490 pmol cyclic AMP per mg protein per 10 min. Addition of a wide range of morphine concentrations (1.33–79.8  $\mu\text{M}$ ) did not inhibit the basal or the  $\text{PGE}_1$ -stimulated enzyme activity. The same results were obtained with lysates preincubated with morphine (2 min, 30 °C) before the AC assay.

Similar negative observations were also made with intact platelets.  $\text{PGE}_1$  (0.14–0.7  $\mu\text{M}$ ) stimulated cyclic AMP accumulation by 1.8- to 10.1-fold over the unstimulated controls. The addition of morphine (2.6–26  $\mu\text{M}$ ) did not affect the unstimulated controls. The addition of morphine (2.6–26  $\mu\text{M}$ ) did not affect the stimulatory action of  $\text{PGE}_1$ . A typical experiment in which the lowest concentration of  $\text{PGE}_1$  (0.14  $\mu\text{M}$ ) was used in combination with 13.3 or 26  $\mu\text{M}$  morphine is given in Table 2.

In direct binding studies of  $^3\text{H}$ -etorphine to platelet lysate preparations, we failed to demonstrate any specific binding. The difference between the amount of  $^3\text{H}$ -etorphine bound in the absence or presence of 10  $\mu\text{M}$  levorphanol was not significantly different from zero (four duplicate determinations performed on each platelet preparation obtained from four donors). Simultaneously with these determinations, and in identical experimental conditions, we also measured the binding of  $^3\text{H}$ -etorphine to a particulate fraction derived from rat corpus striatum as a control tissue. The content of  $^3\text{H}$ -etorphine binding sites in this brain preparation was  $315 \pm 45 \text{ fmol per mg protein}$  ( $n = 4$ ). Binding of  $^3\text{H}$ -etorphine in the presence of 10  $\mu\text{M}$  levorphanol did not exceed 25–40% of the amount bound in the absence of the unlabelled competing ligand.

In conclusion, the inverse relationship of cyclic AMP levels and aggregability of human platelets is now well documented<sup>19</sup>, as  $\text{PGE}_1$ , which stimulates platelet AC<sup>10</sup>, also antagonizes ADP-

induced aggregation<sup>9</sup>. Furthermore, this relationship also seems to hold for nonspecific agents such as heparin and dextran sulphate, recently demonstrated by us to inhibit  $\text{PGE}_1$ -stimulated AC on the one hand and to augment platelet aggregation on the other<sup>14,20–22</sup>. Although opiates act as inhibiting agonists of AC in some cell types of neural origin, we are so far unable to support the suggestion made by Gryglewski *et al.*<sup>11</sup> that 'AC is the common target for  $\text{PGE}_1$  and morphine in platelets as it is in neurones'. We therefore suggest that the presence of opiate receptors in human platelets remains questionable.

This work was supported by grants to A.R. from the Charles E. Smith Family Foundation, the Israel Center for Psychobiology and from the joint research fund of the Hebrew University and Hadassah, the Dr Leon Deutsch Memorial Endowment Fund; to Y.S. from the US-Israel Binational Science Foundation, and to Professor H. R. Lindner by the Ford Foundation and Population Council. Y.S. is the incumbent of the Charles and Tillie Lubin Career Development Chair. We thank Professor H. R. Lindner for helpful discussions and Mrs E. Epstein and M. Kopelowitz for secretarial assistance.

## Induction of diabetes by cumulative environmental insults from viruses and chemicals

Antonio Toniolo, Takashi Onodera, Ji-Won Yoon & Abner Louis Notkins

Laboratory of Oral Medicine, National Institute of Dental Research, National Institutes of Health, Bethesda, Maryland 20205

Encephalomyocarditis virus (EMC) induces diabetes in certain inbred strains of mice by infecting and destroying pancreatic  $\beta$  cells<sup>1,2</sup>, the severity of the diabetes depending on the number of  $\beta$  cells destroyed<sup>3</sup>. In strains of mice resistant to EMC-induced diabetes, insufficient  $\beta$  cells are damaged to alter glucose homeostasis<sup>3,4</sup>. However, diabetes can be produced in many species by streptozotocin, a highly specific  $\beta$ -cell toxin<sup>5</sup>. Here, we used concentrations of streptozotocin that did not produce diabetes, but reduced the  $\beta$ -cell reserve. When strains of mice normally resistant to EMC-induced diabetes were first treated with sub-diabetogenic doses of streptozotocin, then infected with EMC virus, diabetes developed. Furthermore, when mice were infected with viruses such as Coxsackie B3 and B5, which ordinarily produce little if any  $\beta$ -cell damage<sup>6</sup>, diabetes developed if the mice were first treated with sub-diabetogenic doses of streptozotocin. These findings suggest that diabetes may result from cumulative  $\beta$ -cell damage induced by sequential environmental insults.

Male mice, 4–6 weeks old, weighing 20–25 g (Jackson Laboratories or NIH), were used in these experiments. A highly diabetogenic variant of EMC virus, designated D, and a non-diabetogenic variant, designated B, were prepared in secondary mouse embryo cells as described elsewhere<sup>7</sup>. Unless otherwise indicated, the D variant was used in all experiments. Coxsackieviruses B3 (Nancy strain) and B5 (Faulkner strain) (both from American Type Culture Collection) were passaged in cultures enriched with murine pancreatic  $\beta$  cells<sup>8</sup>. The preparation of fluorescein-labelled anti-EMC antibody and the detection of infected islet cells were carried out as described elsewhere<sup>3,4</sup>.

Mice were injected intraperitoneally with a sub-diabetogenic dose of streptozotocin (1 mg per mouse, mixed anomers, Sigma lot 29C-0009), which did not significantly alter glucose homeostasis in preliminary experiments. Twelve days after administration of streptozotocin, mice were infected intraperitoneally with virus. Each animal was then bled four times; glucose from non-fasting animals was measured 7 and 14 days after infection and single-point 60-min glucose tolerance tests were performed 10 and 17 days after infection. Uninfected animals and animals given only streptozotocin were bled at the same time. The weighted results were expressed as the glucose index<sup>9</sup>. An animal was considered diabetic if its glucose index was equal to or exceeded 3 s.d. above the mean of 124 uninfected mice (mean  $\pm$  s.d. =  $163 \pm 23$ ).

Table 1 shows that the glucose index and percentage of animals developing diabetes was increased if diabetes-prone strains of mice<sup>4,10</sup> were treated with sub-diabetogenic doses of streptozotocin before infection with EMC virus. The most striking results were obtained with NIH/Swiss mice in which the glucose index increased from 223 in mice receiving only EMC virus to 442 in mice receiving both streptozotocin and EMC virus, and the percentage of animals developing diabetes rose

from 28 to 92. Increases in the glucose index were also observed in SJL/J and NFS/N mice. The enhancement in diabetes-prone mice suggested that strains of mice which were ordinarily resistant to EMC-induced diabetes<sup>4,10</sup> might become diabetic if first treated with sub-diabetogenic doses of streptozotocin. As seen in Table 1, 18%, 30%, 53% and 100% of C3H/HeJ, C57BL/6J, CBA/J and AKR/J mice, respectively, developed diabetes when treated with streptozotocin and infected 12 days later with EMC virus.

Treatment of mice with a low dose of streptozotocin also led to the induction of diabetes by viruses which ordinarily did not elevate blood glucose levels. Table 2 shows that Coxsackieviruses B3 and B5 produced diabetes in animals which had been treated with a sub-diabetogenic dose of streptozotocin, whereas in untreated animals these viruses produced little if any diabetes. However, the non-diabetogenic B variant of EMC virus<sup>7</sup> did not produce diabetes in either streptozotocin-treated or untreated mice.

To determine whether streptozotocin enhanced virus-induced diabetes by increasing the susceptibility of islet cells (for example, by immunosuppressing the host)<sup>11</sup>, the number of EMC-infected islet cells was determined by staining sections of pancreas with fluorescein-labelled anti-EMC virus antibody<sup>3,4</sup>. Table 3 shows that approximately the same or slightly fewer islet cells were infected in streptozotocin-treated mice as in untreated mice. This suggests that streptozotocin is acting by decreasing the  $\beta$ -cell reserve rather than by increasing the susceptibility of  $\beta$  cells to infection. In fact, microscopic examination of sections of pancreas from mice treated with streptozotocin (1 mg per mouse) showed that some  $\beta$  cells had been destroyed. Furthermore, quantification by radioimmunoassay revealed that the insulin content of the pancreas of mice treated with 1 and 2 mg of streptozotocin was reduced by 15% and 48%, respectively, 12 days later.

**Table 1** Enhancement of virus-induced diabetes by treatment with sub-diabetogenic doses of streptozotocin

In the normal animal there are enough  $\beta$  cells to maintain glucose homeostasis—only when the  $\beta$ -cell reserve is sufficiently depleted does hyperglycaemia develop<sup>5</sup>. Our experiments show that, by reducing the  $\beta$ -cell reserve with a sub-diabetogenic dose of streptozotocin, it is possible to produce diabetes in strains of mice which are usually resistant to EMC-induced diabetes. In previous experiments with EMC virus, we found that over 40% of the  $\beta$  cells in the pancreas of diabetes-prone SJL/J mice contained viral antigens, as opposed to less than 12% of  $\beta$  cells from diabetes-resistant CBA/J, AKR/J and C57BL/6J mice<sup>4</sup>.

| SJL/J        | —                                 | 41  | 44  | 12  |

\* Each mouse received 1 mg of streptozotocin intraperitoneally 12 days before infection with  $1.0 \times 10^4$  PFU of the D variant of EMC virus.

<sup>†</sup> At 2, 3 and 4 days after infection, sections of pancreas from groups of three mice were stained with fluorescein-labelled anti-EMC antibody and the approximate number of cells containing viral antigens determined. At each time point, an average of 40 islets and over 2,000 cells were counted.

It was concluded that the latter strains did not develop diabetes because  $\beta$ -cell damage was insufficiently extensive. The experiments reported here show that neither a low dose of streptozotocin alone nor EMC virus alone produced diabetes, but the combined insult resulted in diabetes. Similarly, Coxsackieviruses B3 and B5 produced relatively little  $\beta$ -cell damage in untreated animals, but when the  $\beta$ -cell reserve was reduced by a low dose of streptozotocin, the animals developed diabetes.

Depletion of  $\beta$  cells in mice by sub-diabetogenic doses of streptozotocin may provide a useful model for identifying other diabetogenic viruses, especially those which infect and destroy only minimal numbers of  $\beta$  cells. The enhancement of virus-induced diabetes by low doses of streptozotocin also raises the possibility that in humans a series of viral infections or other environmental insults (for example, chemicals, drugs, toxins), each producing some  $\beta$ -cell damage, finally results in overt insulin-dependent diabetes once the  $\beta$ -cell reserve has been sufficiently depleted.

Genetic factors are also known to play an important role in the development of insulin-dependent diabetes<sup>2</sup>, but precisely how is not clear. If the result is a relative deficiency of  $\beta$  cells or an impaired capacity to regenerate damaged  $\beta$  cells, then viruses, chemicals or drugs might more readily produce diabetes in these already deficient individuals.

## Tolerance as an active process

Judy M. Teale & Norman R. Klinman

The Department of Cellular and Developmental Immunology, Scripps Clinic and Research Foundation, La Jolla, California 92037

The clonal deletion model proposed by Burnet<sup>1</sup> and Lederberg<sup>2</sup> and expanded by Nossal<sup>3</sup> was one of the first theories concerning the nature of tolerance to self constituents. The model proposed that during the maturation of lymphocytes into immunocompetent cells, there is a sensitive differentiation stage whereby contact with antigen results in specific inactivation of the cell. Experimental evidence indicates that neonatal or immature B lymphocytes are indeed different from adult lymphocytes in their extreme sensitivity to tolerance induction even at low antigen concentrations and with antigens that are normally immunogenic<sup>3–9</sup>. The present study examines the mechanism of this tolerance phenomenon by determining whether or not tolerance of immature B cells is an active process and what specific interactions can induce this event. We used various putative inhibitors of tolerance induction in the splenic focus assay<sup>4</sup> which examines the tolerance susceptibility of individual B cells. The results suggest that tolerance requires protein synthesis and that this process is initiated only after a minimum threshold affinity of binding occurs between antigen and cell-surface receptor with subsequent receptor interlinkage.

Nonimmune neonatal or adult spleen cells were injected intravenously into irradiated (1,300R) BALB/c recipients that had been primed with 0.1 mg of *Limulus polyphemus* haemocyanin(Hy) 6–12 weeks previously. At 16–18 h after transfer, fragment cultures derived from the recipient spleens were prepared and incubated for 18 h in Dulbecco's modified Eagle's medium (DMEM) with or without the presence of the tolerogen dinitrophenol-ovalbumin (DNP<sub>10</sub>-OVA) at  $10^{-6}$  M DNP<sup>4</sup>. To study the inhibition of tolerance induction, concentrations of putative inhibitors were chosen which, if removed after the first 18 h of culture and before antigenic stimulation, had no inhibitory effect on stimulation. Thus, by adding DNP<sub>10</sub>-OVA in the presence or absence of the inhibitors for the first 18 h of culture, the effect of each inhibitor on tolerance could be determined. The DNP<sub>10</sub>-OVA and/or inhibitors were washed out after 18 h and DMEM containing the antigen DNP<sub>10</sub>-Hy ( $10^{-6}$  M DNP)<sup>4</sup> was added. Culture supernatants were collected on days 10, 13 and 17 and analysed for the presence of anti-DNP antibody by a

**Table 1** A requirement for protein synthesis during tolerance induction

| Age of donor cells | Experimental group                 | % Of control response* |
|--------------------|------------------------------------|------------------------|
| 1–3 day neonatal   | Tolerogen (DNP <sub>10</sub> -OVA) | 28.5 ± 7.0             |
| 1–3 day neonatal   | Puromycin alone                    | 87.5 ± 12.7            |
| 1–3 day neonatal   | Tolerogen + puromycin              | 92.1 ± 3.8             |
| 10–12 week adult   | Tolerogen (DNP <sub>10</sub> -OVA) | 100                    |
| 10–12 week adult   | Puromycin alone                    | 77.0                   |
| 10–12 week adult   | Tolerogen + puromycin              | 77.0                   |

Adult or neonatal spleen cells were transferred to carrier-primed recipients ( $4\text{--}6 \times 10^6$  donor cells per recipient). Fragment cultures were incubated for 18 h in the presence or absence of the tolerogen DNP<sub>10</sub>-OVA and in the presence or absence of the inhibitor puromycin ( $25 \mu\text{g ml}^{-1}$  for adult groups,  $20 \mu\text{g ml}^{-1}$  for neonatal groups). The tolerogen and/or inhibitor was/were washed out after 18 h and stimulated for 3 days with DNP-Hy ( $10^{-6}$  M DNP). Supernatants were collected on days 10, 13 and 17 and the frequency of anti-DNP-secreting clones was detected by RIA. Data are expressed as per cent of control response.

\* Neonatal groups represent the means of three experiments ± s.e.m. Adult groups represent the average of two experiments.

solid-phase radioimmunoassay (RIA). The anti-DNP antibody was detected in RIA through the use of rabbit anti-mouse immunoglobulin followed by  $^{125}\text{I}$ -labelled purified goat anti-rabbit immunoglobulin<sup>10</sup>.

To determine if tolerance of neonatal B cells represents an active process which would require a trigger, the effect of the protein biosynthesis inhibitor, puromycin, was studied. It was assumed that any effect on tolerance observed would be due to the effect of puromycin on the neonatal donor B cells, although there is a remote possibility that the highly irradiated cells also present in the fragment are involved in tolerance and, therefore, would be affected by puromycin. Table 1 shows that puromycin substantially inhibits the induction of tolerance by DNP<sub>10</sub>-OVA resulting in stimulation and production of anti-DNP-secreting clones at a frequency close to that observed in control cultures. On the other hand, when adult B cells were assayed using the same experimental procedure, they were found to be resistant to tolerance induction as reported elsewhere<sup>4,5</sup> and the addition of puromycin was, therefore, inconsequential. The requirement for protein biosynthesis during tolerance induction of neonatal B cells provides compelling evidence that tolerance is an active process and cannot be explained simply by passive phenomena such as receptor blockade<sup>11,12</sup>.

Our next concern was the mechanism by which immature B cells are induced into the tolerance mode, including the antigen-binding prerequisites of the tolerance trigger. Although previous studies had indicated that multivalent antigens maximize tolerance induction<sup>4,13</sup>, a requirement for multivalent interactions during tolerance had not been tested directly. Thus, the effect of various concentrations of DNP-L-lysine on DNP<sub>10</sub>-OVA-induced tolerance was ascertained. Table 2 indicates that a 10-fold higher molar concentration of DNP-L-lysine as compared with the molar concentration of DNP present on DNP<sub>10</sub>-OVA markedly inhibits tolerance induction. Inhibitory effects of equal molar concentrations and 10-fold lower concentrations of DNP-L-lysine can also be seen. This finding demonstrates the necessity for multivalent interactions between tolerogen and cell-surface receptors. As DNP-L-lysine can bind receptors with a high enough affinity to inhibit tolerance induced by DNP presented multivalently, it is inferred that binding alone is not sufficient to trigger tolerance but that receptor interlinkage must be achieved.

It is well known that the antibody products from most DNP-specific B cells can bind to the hapten trinitrophenol (TNP)<sup>14,15</sup>. However, TNP antigens seem incapable of stimulating primary DNP-specific B cells<sup>14,15</sup> or of tolerizing DNP-specific immature B cells<sup>4</sup>. Therefore, it was of interest to determine if various concentrations of TNP-L-lysine could inhibit tolerance induction by DNP<sub>10</sub>-OVA (Table 2). Similar to the experiments using DNP-L-lysine, a 10-fold higher molar concentration of TNP-L-lysine as compared with the molar concentration of DNP on DNP<sub>10</sub>-OVA resulted in almost complete inhibition of tolerance. However, equal and 10-fold lower concentrations of TNP-L-lysine resulted in little or no

inhibition of tolerance induction, indicating that a higher ratio of TNP to DNP is necessary to inhibit tolerance than when the homologous hapten is used as an inhibitor. This suggests that TNP-L-lysine binds to DNP-specific B cells but at a lower affinity than DNP-L-lysine. As TNP-L-lysine does bind to the receptors of DNP-specific B cells, the failure of TNP antigens to trigger DNP-specific B cells is probably directly related to the affinity with which it is bound by the cell's receptors.

**Table 3** Inhibition of DNP<sub>12</sub>-OVA-induced tolerance with TNP<sub>17</sub>-BSA

| Experimental treatment  | % Of control response* |
|---|------------------------|
| DNP response  |                        |
| Tolerogen alone (DNP <sub>10</sub> -OVA, $10^{-6}$ M)                                   | 27.8 ± 7.8             |
| Tolerogen (DNP <sub>10</sub> -OVA, $10^{-6}$ M) + TNP <sub>17</sub> -BSA ( $10^{-5}$ M) | 89.6 ± 10.5            |
| TNP <sub>17</sub> -BSA ( $10^{-5}$ M)   | 100                    |
| TNP response  |                        |
| Tolerogen (TNP <sub>17</sub> -BSA, $10^{-6}$ M)   | 33.3                   |

For the DNP response, the same procedure was used as described in Table 1 legend except TNP<sub>17</sub>-BSA was used as inhibitor. For the TNP response, TNP<sub>17</sub>-BSA was used as tolerogen and TNP<sub>10</sub>-Hy ( $10^{-6}$  M) as antigen.

\* Results represent the mean ± s.e.m. of three experiments. The results represent the average of two experiments where the s.e.m. is omitted.

To test directly the postulate that TNP antigens bind to DNP-specific B cells but fail to trigger these cells because the affinity of such binding is too low, an excess of TNP presented multivalently with bovine serum albumin (TNP<sub>17</sub>-BSA) was tested for its ability to inhibit DNP<sub>10</sub>-OVA-induced tolerance. As shown in Table 3, TNP<sub>17</sub>-BSA inhibits DNP<sub>10</sub>-OVA-induced tolerance demonstrating its ability to bind to DNP-specific B cells yet its inability to tolerize these cells. Also included in Table 3 are data which show that the same preparation of TNP<sub>17</sub>-BSA is an effective tolerogen for TNP-specific cells. The ability to distinguish between two closely related haptens demonstrates that the tolerance trigger is an extremely specific one and that this specificity apparently depends on a minimum threshold affinity of binding between tolerogen and receptor. Below this threshold the tolerogen may not bind to the receptor long enough to achieve stable interlinkage of receptors<sup>16</sup>.

If one compares the analyses of the apparent binding requisites of stimulation with the present findings on tolerance, obvious parallels can be drawn between the two processes. First, despite a few reports to the contrary<sup>17-19</sup>, monovalent haptens seem unable to induce stimulation<sup>13,20,21</sup>, and in fact, can inhibit stimulation induced by the same hapten presented multivalently<sup>16</sup>. Thus, stimulation, like tolerance, apparently requires multivalent determinant presentation and receptor interlinkage<sup>13,16,20-22</sup>. Whether or not this is analogous to the receptor patching-capping-endocytosis cycle induced by anti-immunoglobulin<sup>23</sup> or some antigens<sup>23-25</sup> is unclear as considerably greater concentrations of either anti-immunoglobulin or antigen are required to induce this cycle than are required to induce either stimulation or tolerance<sup>25</sup>. In any event, more than receptor modulation is required to achieve both stimulation and tolerance as protein synthesis is required (ref. 26 and this work), a requirement not found necessary for the patching-capping-endocytosis cycle<sup>23</sup>.

Similarly, both the tolerance and the stimulation seem to be dependent on a minimum threshold affinity of binding between antigen and receptor. Earlier studies demonstrating the affinity dependence of stimulation showed that increasing concentrations of antigen above  $5 \times 10^{-7}$  M did not stimulate a higher frequency of cells nor did it stimulate more cells producing lower-affinity antibody<sup>15,16</sup>. Clearly, antigen-binding cells did not correlate with cells capable of being triggered. Correspondingly, as mentioned previously, it was found that TNP on an

**Table 2** Inhibition of the tolerance trigger by monovalent haptens

| Experimental treatment                                    | % Of control response* |            |
|---|------------------------|------------|
|   | Neonates               | Adult      |

| Tolerogen + $10^{-6}$ M DNP-L-lysine                      | 77.3 ± 9.1             | 100 ± 0    |
| Tolerogen + $10^{-5}$ M DNP-L-lysine                      | 95.8 ± 3.4             | 85.2 ± 8.7 |
| Tolerogen + $10^{-7}$ M TNP-L-lysine                      | 25.0                   | Not done   |
| Tolerogen + $10^{-6}$ M TNP-L-lysine                      | 53.5 ± 10.4            | 100        |
| Tolerogen + $10^{-5}$ M TNP-L-lysine                      | 94.3 ± 2.9             | 100        |

The same procedure was used as described in Table 1 legend except that the indicated concentrations of monovalent haptens were used as inhibitors.

\* Results of three experiments ± s.e.m. Results represent the means of two experiments where s.e.m. is omitted.

appropriate carrier could not activate DNP-specific cells even though the antibody products cross-react<sup>13,14</sup>. Therefore, the stimulation trigger, like the tolerance trigger, is an extremely specific one that seems to be a consequence of the requirement for a minimum affinity of binding between the antigen and receptor. It should be emphasized that stimulation is a more complex process than tolerance. Stimulation involves not only antigen-receptor interaction but also interactions with other cell-surface receptors and/or cell types (for example, macro-

phages, T cells). Thus, these experiments on stimulation are open to other interpretations. In comparison, the tolerance trigger seems to be relatively simple, involving only antigen-receptor interactions. Thus, for the first time it has been possible to affix a requirement for both multivalency and a minimum binding affinity to the triggering of B cells by antigen.

## Major anti-paternal alloantibody induced by murine pregnancy is non-complement-fixing IgG1

Stephen C. Bell & W. David Billington

Reproductive Immunology Group, Department of Pathology, The Medical School, University of Bristol, Bristol BS8 1TD, UK

Maternal humoral immune responses against antigens of the genetically alien embryo have been reported in several mammalian species, including man, although little is known of the biological relevance of this phenomenon. In the mouse, only females of certain inbred strains mated repeatedly with an allogeneic male produce antibody directed against paternally inherited fetal histocompatibility antigens, as assessed by haemagglutination techniques<sup>1-4</sup>. It has been suggested that this characteristic of the female is associated with the H-2<sup>b</sup> haplotype<sup>3</sup>, although some reports indicate that it also extends to other H-2 types<sup>5</sup>. Potentially deleterious complement-dependent cytotoxicity, albeit at low levels, has been claimed to be associated with this alloantibody, but we have been unable to detect any such activity in a large number of maternal sera<sup>6</sup>. Four IgG isotypes (IgG1, IgG2a, IgG2b and IgG3) have been identified and shown to occur in the serum of normal animals<sup>7,8</sup>. Despite their similar physicochemical properties, which complicate purification procedures, the availability of immunoglobulin-secreting plasmacytomas has made possible the preparation of isotype-specific antisera<sup>9,10</sup>. Using these antisera in a modified haemadsorption assay<sup>11</sup>, we have now demonstrated that the major alloantibody response induced by murine pregnancy involves the non-complement-fixing IgG1 subclass. This is a noncytotoxic antibody with potentially protective (enhancing) properties<sup>12</sup>.

Mature C57BL (H-2<sup>b</sup>) inbred female mice were caged with fertile CBA/Ca (H-2<sup>k</sup>) males and pregnancies recorded following observation of vaginal plugs. Between 1 and 7 days after birth of their third litter, females were bled by cardiac puncture and the serum stored at -20°C. A group of C57BL animals were injected intraperitoneally (i.p.) with 3 × 10<sup>7</sup> spleen cells from CBA/Ca males in 0.2 ml of saline, at weekly intervals for 5 weeks. Fourteen days after the final injection, animals were bled by cardiac puncture and serum stored at -20°C. The IgG subclass of the alloantibody response was determined by a modified haemadsorption assay<sup>11</sup>, using sheep red blood cells (SRBCs) coated with rabbit anti-immunoglobulin, anti-IgG1 or

anti-IgG2 (Bionetics). Fibroblasts obtained by trypsinization of CBA/Ca 14-day embryos were cultured in immunofluorescence trays (Sterilin). After incubation with serial double dilutions of sera, plates were incubated with coated SRBCs. The presence of alloantibody was indicated by SRBC binding to the fibroblasts.

The sera from all nine multiparous females exhibited titres of alloantibody of the IgG1 subclass equivalent to the titres obtained with total immunoglobulin reagent (Fig. 1a). This indicates that approximately all the alloantibody present can be accounted for by IgG1 alloantibody. Although IgG2 alloantibody was detected in seven of the sera, this was present at only 1/32 to 1/8 of the levels of the IgG1 alloantibody. To compare this response with one induced by a well-documented route of immunization, sera from animals injected i.p. with allogeneic spleen cells were analysed. As shown in Fig. 1b, in three of the six sera the immunoglobulin levels could largely be accounted for by the IgG2 alloantibody (sera nos 4-6). In all cases, alloantibody of the IgG1 subclass was also detected, ranging from titres equal to those of the IgG2 alloantibody down to 1/4 of these levels. The finding in pregnancy of IgG1 alloantibody levels largely equivalent to those of the total immunoglobulins made it unnecessary, for the present purposes, to assess the precise level of any IgG3 response, especially as this is also believed to be a non-complement-fixing subclass. No cytotoxic activity was detected in any of the maternal sera.

The finding that the major alloantibody response directed against the paternally inherited fetal histocompatibility antigens in multiparous females is of the IgG1 subclass, and that no complement-dependent cytotoxicity is detectable in these sera, suggests that it represents a non-complement-fixing IgG1 subclass. All IgG1 antibodies have been assumed to be unable to fix complement<sup>10,13</sup>, although a cytotoxic complement-fixing IgG1 antibody has recently been demonstrated in mice injected intravenously with SRBCs<sup>14</sup>. The alloantibody induced by i.p. immunization was cytotoxic, and this seems attributable to the predominance of IgG2 alloantibody. Although seven of the multiparous females also produced IgG2 alloantibody the levels were clearly too low to effect cytotoxicity. It is interesting that the levels of IgG1 antibody in the immunized mice were similar to those in the pregnant females, for this suggests there may be a selective suppression of complement-fixing IgG2 antibody in pregnancy.

We know of no comparable data on antibody subclass distribution in pregnancy for other species. In the human, it is well established that antibodies with cytotoxic activity (which are used as HLA-typing reagents) may be detected in up to 15% of primiparous and 60% of multiparous women. However, in almost all cases the titre of such cytotoxic antibody is very low

**Fig. 1** Levels of anti-CBA/Ca ( $H-2^k$ ) alloantibody as total immunoglobulin, IgG1 and IgG2 subclasses in sera from nine multiparous C57BL ( $H-2^b$ ) females mated with CBA/Ca males (a) and six C57BL animals repeatedly immunized i.p. with CBA/Ca spleen cells (b). CBA/Ca fibroblasts ( $1 \times 10^5$  cells per well of immunofluorescence tray) were cultured for 24 h and, after removal of culture medium, serial double dilutions of test sera were incubated with the monolayer for 30 min. Sera were diluted with culture medium. Monolayers were then incubated for 30 min with SRBCs coated sequentially with mouse anti-SRBC sera and rabbit anti-mouse immunoglobulin, IgG1 or IgG2. After washing, monolayers were examined for SRBC binding. The final dilution of sera with which binding was obtained was considered to represent the alloantibody titre. Results shown are the reciprocal of the alloantibody titre obtained with □ anti-immunoglobulin; ■ anti-IgG1; ▨ anti-IgG2.

(usually less than 1/32) and it is quite possible that this does not represent the major alloantibody response. Further studies with different assay systems are required to determine whether there is a significant non-complement-fixing antibody response as in the mouse.

The factors responsible for regulation of the type of antibody response have not been fully defined, although the nature of the antigen and the route of immunization are certainly major determinants. In allogeneic murine pregnancy much information is available on the ontogeny and tissue distribution of  $H-2$  antigens on the fetus and placenta<sup>11</sup>, but the precise source of the stimulatory antigen and the timing and route of maternal immunization are unknown. If the factors that favour a predominantly non-complement-fixing IgG1 antibody response could be determined, this would throw light on the mechanisms responsible for the survival of the fetus as an intra-uterine allograft, especially those directly implicating maternal alloantibody or antigen-antibody complexes in the blocking of cell-mediated immune reactions. The present findings also caution

against the use of experimentally hyperimmunized female mice in studies on the role of pregnancy-induced maternal alloantibody in other feto-maternal immunological interactions.

We thank Mrs Sue Watts for technical assistance and the Rockefeller Foundation for financial support.

## Spontaneous remission of autoimmune encephalomyelitis is inhibited by splenectomy, thymectomy or ageing

Avraham Ben-Nun, Yacov Ron & Irun R. Cohen

Department of Cell Biology, The Weizmann Institute of Science, Rehovot, Israel

**Experimental autoimmune encephalomyelitis (EAE) can be induced in genetically susceptible animals by injecting them with basic protein of myelin (BP) in a suitable adjuvant<sup>1</sup>. EAE in adult Lewis rats is expressed clinically by acute paralysis and histologically by mononuclear cell infiltration of the central nervous system. Most rats spontaneously recover from EAE and show little or no damage to myelin<sup>2</sup>. We report here that chronic progressive EAE with marked myelin lesions can be induced by a single injection of BP in complete Freund's adjuvant in intact 13-month old rats, or in 4-month old rats provided they have been splenectomized. Juvenile 2½-month old rats recover spontaneously despite splenectomy. Thymectomy of young adult rats leads to relapsing EAE. These results illustrate that the clinical course of EAE is markedly influenced by age and integrity of immune organs. Furthermore, they provide an experimental model with features similar to those of chronic relapsing disease of the nervous system of man.**

Eleven to twelve days following a single injection of BP emulsified in complete Freund's adjuvant, young adult Lewis rats develop paralysis, primarily of the tail and hind legs. Histological examination of the brain typically shows perivascular infiltration of mononuclear cells. The myelin is usually intact, or only slightly damaged, and within 5–6 days most rats spontaneously recover. A proportion of female rats has been reported to relapse after recovery<sup>3</sup> and the incidence of relapses can be increased by adrenalectomy after the onset of EAE<sup>4</sup>. Past experience<sup>2</sup> shows that relapses of EAE in young rats are not frequent and chronic EAE is rare.

EAE has been proposed as a model of human demyelinating diseases, such as multiple sclerosis<sup>5</sup> but this condition is characterized by a relapsing clinical course and extensive damage to myelin. Therefore rat EAE, as an acute monophasic disease, with little evidence of demyelination, is not a very faithful model of multiple sclerosis. The mechanisms responsible for recovery from EAE have not been identified. The thymus and spleen are organs which function in regulating some aspects of immune reactions<sup>6,7</sup>. To investigate the possible role of these organs in recovery we surgically removed the thymus from 6-week old Lewis rats and splenectomized 3-month old rats. When these rats were 4 months old we injected them with BP in adjuvant.

Untreated rats, or controls that underwent sham thymectomy or sham splenectomy, all developed EAE, judged by overt paralysis (see Table 1), and 10% of the rats died acutely. The remaining 90% were kept alive by individual supportive care with food and water, and all had a full clinical recovery. Histological examination of the brains 32 days after induction of EAE revealed perivascular infiltration of mononuclear cells. There was no evidence of myelin damage in these rats.

Four month old rats which had undergone thymectomy before induction of EAE demonstrated a different type of disease. Of the eight rats which survived the acute onset of EAE, three showed persistent paralysis. The other five recovered at about day 17, but all showed a relapse of clinical paralysis 3 days later, on day 20. Four of these five rats recovered from this relapse on day 24 but one had persistent paralysis. All the rats had marked perivascular infiltrates and all showed severe disruption of myelin.

Rats which had been splenectomized before induction of EAE developed acute disease, from which 2 out of 10 died. The remaining eight rats did not recover and showed persistent paralysis of the hind limbs until they were killed on day 32. The brains showed severe perivascular infiltration and myelin damage. Rats which had been thymectomized at 6 weeks then splenectomized at 3 months behaved about the same as those which had been splenectomized but not thymectomized.

It has been reported that spontaneous relapses are more common in 6-month old than in 3-month old rats<sup>8</sup>. Table 2 shows the results of an experiment in which we compared the responses of groups of rats which were splenectomized at 1½, 3 or 12 months. EAE was induced 1 month later. Rats aged 2½ months that had not died of acute EAE recovered, and no

| Thymectomy    |              |           |             |              |                    |                       |         |           |                       |           |                    |
| + splenectomy | 10           | 10/10     | 3/10        | —            | 0/7                | 7/7                   | —       | —         | —                     | —         | ++++               |

Thymectomy and splenectomy of female Lewis rats were performed under Nembutal anaesthesia (Veterinary Nembutal; Abbot), 60 mg per kg body weight. Thymectomies were done when rats were 6 weeks old and splenectomies when they were 3 months old. The animals were injected to induce EAE at the age of 4 months. Basic protein (500 µg ml<sup>-1</sup>) extracted from guinea pig spinal cords was emulsified with an equal volume of Freund's adjuvant containing 4 mg ml<sup>-1</sup> H37Ra *Mycobacterium tuberculosis* (Difco). Each rat was injected with a total volume of 0.1 ml emulsion, containing 25 µg of basic protein, equally divided between the two hind footpads. The animals were examined daily for unequivocal signs of EAE which we considered to be overt paralysis of the tail and hind legs. Chronic EAE refers to paralysis that was unremitting from its onset until the experiment was terminated 32 days after injection. The surviving rats were killed and their brains and segments of spinal cord fixed for histological examination in 10% formalin, processed and embedded in paraffin for staining by haematoxylin and eosin, or by Luxol fast blue-periodic acid Schiff, to detect myelin damage. Pathology was scored on a scale + to +++++. (++++ Indicates disruption of myelin and severe mononuclear cell infiltrates in perivascular and periventricular areas, and in the parenchyma of the nervous tissue: spinal cord, brain stem, cerebellum and cerebrum. +++ Indicates no damage to myelin but severe and extensive infiltration as above. ++ Indicates moderate infiltration limited to perivascular areas with a spotty distribution. + Indicates mild perivascular infiltrates observed in at least one area.)

Table 2 Chronic or relapsing EAE as a function of age or splenectomy

| Age (months) | Treatment   | Day of onset | Acute EAE |             | Recovery Day | Recovery Incidence | Chronic EAE Incidence | Relapse |           | Recovery from relapse Incidence | Grade of pathology |
|--------------|-------------|--------------|-----------|-------------|--------------|--------------------|-----------------------|---------|-----------|---------------------------------|--------------------|
|              |             |              | (Total)   | (Mortality) |              |                    |                       | Day     | Incidence |                                 |                    |
| 2½           | None        | 11           | 8/8       | 2/8         | 17           | 6/6                | 0/6                   | —       | 0/6       | —                               | ++                 |
|              | Sham        |              |           |             |              |                    |                       |         |           |                                 |                    |
|              | splenectomy | 12           | 8/8       | 2/8         | 16           | 6/6                | 0/6                   | —       | 0/6       | —                               | ++                 |
| 4            | Splenectomy | 11           | 8/8       | 3/8         | 17           | 5/5                | 0/5                   | —       | 0/5       | —                               | ++                 |

Splenectomy of female Lewis rats was carried out at 1½, 3 or 12 months of age and EAE was induced 1 month later, as described in the legend to Table 1. Each age group was studied in a separate experiment. Repeat experiments involving rats of these ages all produced essentially the same results.

relapses were observed, whether or not the rats had been splenectomized a month earlier. Untreated or sham splenectomized 4-month old rats all developed acute EAE with about 10% mortality. All the surviving rats recovered without relapsing and their brains showed perivascular infiltrates with no damage to myelin. Similar to results shown in Table 1, the splenectomized rats that survived acute EAE all developed chronic paralysis and showed disruption of myelin on histological examination.

The 13-month old Lewis rats that were untreated or sham-splenectomized showed a relapsing or chronic course of EAE. Of the 13 rats that survived acute EAE in both of these groups 9 had unremitting, chronic paralysis. The four rats that recovered all suffered a relapse from which none recovered. Thirteen month old rats that had been splenectomized developed a chronic form of EAE similar to that of 3-month old splenectomized rats. These all had severe perivascular infiltrates and myelin damage.

EAE was also induced in unsplenectomized 15-month old rats. Of 14 rats inoculated, 5 died with acute EAE and 9 had chronic unremitting paralysis of the hind legs for 45 days, at which time the experiment was terminated.

It has been reported that male Lewis rats are more resistant to relapse of EAE than females<sup>3</sup>, but we have not yet had the opportunity to study the influence of sex on the effects of age or splenectomy.

In contrast to EAE in rats, EAE induced in guinea pigs is usually acutely fatal. However, injection of very young (2–4-week old) guinea pigs with guinea pig spinal cord in adjuvant produced a chronic or relapsing form of EAE after a relatively long latent period<sup>9,10</sup>. Although there are differences between the rat and guinea pig models of EAE, these results emphasize the importance of an animal's age to the clinical course of EAE. The mechanisms by which age affects expression of EAE are probably complex, because age modifies the functions of organ systems which influence EAE, such as the immune and endocrine systems. It is conceivable that changes in the expression of EAE with age are related to changes in the function of the spleen.

Age also seems to have an important influence on the outcome of thymectomy. As we have shown (Table 1), thymectomy of 4-month old rats increases the severity of EAE. This contrasts with the effect of neonatal thymectomy, which has been observed to decrease markedly susceptibility to induction of EAE<sup>11</sup>.

The effects of thymectomy and splenectomy indicate the importance of immune physiology in the clinical course of EAE. We have found (in preparation) that recovery from acute EAE is associated with suppression, in the draining lymph nodes, of the

proliferative response of T lymphocytes to a particular determinant of BP. The reactivity to other determinants on the BP molecule is undiminished during recovery. This suggests that the spleen and thymus may be involved in the physiological suppression of the immune response to a critical determinant on BP. However, splenectomy of 1½-month old rats failed to interfere with recovery from EAE induced a month later (Table 2). We have also observed that splenectomy of 3-month old rats 1 week rather than 4 weeks before induction of EAE did not prevent recovery from acute EAE (data not shown). Therefore, the task of the spleen is modified by the age of the subject and the timing of EAE induction. This suggests that the populations of cells mediating recovery are not always resident in or dependent on the spleen.

Our results suggest that defects in regulation of an immune response can transform what might otherwise be a self-limited insult into a chronic or relapsing disease of the nervous system. It is conceivable that multiple sclerosis or other progressive or relapsing diseases could be triggered acutely by a virus or some other noxious agent and be perpetuated by a defect in immune regulation. Subacute sclerosing panencephalitis, a chronic degeneration of the brain associated with infection by measles virus, has been suggested as an example of diseases involving irregularity of the immune response<sup>12</sup>. It is possible that our experimental models of chronic or relapsing EAE might provide a means of identifying immune mechanisms regulating recovery from an autoimmune process and thus, a useful experimental approach to certain clinical problems such as multiple sclerosis.

We thank Mr H. Otmi and Mr M. Margalit for their technical assistance, and Professor M. Feldman for his support. This study was supported by a grant from the Stiftung Volkswagenwerk, Hannover.

## Precursor and effector phenotypes of activated human T lymphocytes

L. Fainboim, C. Navarrete & H. Festenstein

Department of Immunology, London Hospital Medical College, Turner Street, London E1 2AD, UK

In mice, thymus-derived lymphocytes are differentiated into functional subclasses by their cell surface antigens. The Ly 1 determinants are present on T cells with a helper function, whereas Ly 2 and Ly 3 antigens are expressed on the surface of lymphocytes with suppressor or cytotoxic functions<sup>1-6</sup>. In man also, T-cell subsets have been identified using allo- and heteroimmune sera and, more recently, using monoclonal antibodies, which seem to identify helper and suppressor or cytotoxic subpopulations<sup>7-9</sup>. The major histocompatibility system (MHS)-encoded Ia antigens belong to several polymorphic families of membrane associated glycoproteins originally found on B lymphocytes<sup>10,11</sup>; however, they have also been shown to be markers for suppressor T cells in mice<sup>12,13</sup>. Recent studies have shown that in both mouse and man, T cells activated by a mixed lymphocyte reaction or by mitogens become Ia<sup>+</sup><sup>14-18</sup>. Furthermore, some human T lymphoid cells, either freshly isolated from peripheral blood or after *in vitro* activation by lectins<sup>19-21</sup> or alloantigens<sup>22-24</sup>, possess suppressor properties. We report here the phenotype of a T suppressor-cell subpopulation which was induced in long-term culture of lymphoid cells after activation with phytohaemagglutinin (PHA). Our results suggest that a subset of T cells was progressively expanded over a period of 8 days in culture and that, with the expression on the surface of these cells of 'Ia-like' antigens, they acquired the capacity to suppress the proliferative response of syngeneic or allogeneic lymphocytes to alloantigens or mitogens.

Peripheral blood lymphocytes (PBL) from six healthy donors were stimulated *in vitro* with PHA. The cultures were maintained for 30 days by repeatedly changing the culture medium. After 3, 8, 11, 18 and 23 days,  $5 \times 10^6$  activated cells were taken from the suspension cultures and divided into two aliquots—one for assaying the suppressor activity in culture experiments, and the other for serological investigation of surface antigens on the activated cells.

To study their influence on syngeneic cells, activated cells were irradiated and mixed with equal numbers of syngeneic lymphocytes. Three of these mixed syngeneic/activated cell (SAC) cultures gave similar kinetic patterns with an exponential decline in stimulation: in donor V.A., SACs dropped to background stimulation by day 11, and in donors R.H. and J.A. by day 18 (Table 1). These results suggest that the decline of DNA synthesis in the SACs could be due to the development of suppressor cells. To test this, activated cells were added to cultures of normal lymphocytes stimulated either by purified protein derivative (PPD) or alloantigens. In SACs, reactions were prominent up to day 11, so that potential suppressor activity by J.A.- and R.H.-irradiated peripheral activated lymphocytes (IPALs) on PPD transformation could only be tested with '18-day' IPALs. Syngeneic PBL cultures mixed with '18-day' IPALs then stimulated with PPD were clearly suppressed by R.H., J.A. and V.A., but the suppressor V.A. IPALs were already present on day 8 after activation (Table 1).

Results from mixed lymphocyte culture (MLC) experiments designed to test the suppressor properties of '18-day' (experiment 1) and '23-day' (experiment 2) IPALs are shown in Table 2. These experiments have been repeated several times using frozen cells from '23-day' IPALs, with similar results. The suppressor effects of the IPALs were effective on syngeneic

R.H. and V.A., and also on allogeneic normal lymphocytes (LF).

The resting cells from three different donors were typed for the expression of DR antigens using the method of van Rood *et al.*<sup>25</sup>, and the PHA-activated cells were typed using acridine orange and ethidium bromide at the end of the incubation period. Typings were done using alloantisera from the 7th and 8th International Workshops. Activated T cells were negative for DR antigens when tested on days 3 and 4 after activation, but were positive on day 8. In agreement with a previous report<sup>15</sup>, they expressed the same DR specificities present on the B cells of their resting lymphocytes. When the number of Ia<sup>+</sup> cells was scored using two different anti-Ia monoclonal antibodies (McAB)—DA2 and 62-3-34 (ref. 26)—the number of donor RH Ia<sup>+</sup> cells dropped from 28% on day 0 to become negative on day 3, and from day 8 progressively expanded to 83% on day 23 (Table 3). Similar patterns were observed with donors N.Y. (65% Ia<sup>+</sup>) and A.A. (51% Ia<sup>+</sup>).

**Fig. 1** Suppressor effect on an MLC by different cell numbers of an activated T cells subset.  $20 \times 10^7$  day 23 activated cells were treated with 1:25 (final dilution) of DA2 for 30 min at room temperature, washed twice and incubated with 1:20 dilution of a rabbit anti-mouse FITC conjugated IgG. The cells were fractionated into weakly reactive (the lower 20% of fluorescence Ia<sup>-</sup>) and strongly reactive (the upper 60% of fluorescence Ia<sup>+</sup>) in a fluorescence-activated cell sorter (FACS-1). The MLC was carried out as described in the legend to Table 2. RH was used as responder and irradiated LF as stimulator. Different concentrations of irradiated normal syngeneic cells (▲), Ia<sup>+</sup> (□), Ia<sup>-</sup> (●) or total unfractionated activated cells (Δ) were added to the MLC.

The activated cells were then typed for the expression of the TH2 marker, which had previously been reported to react with a small subset of T peripheral blood lymphocytes with suppressor properties<sup>8</sup>. The number of TH2<sup>+</sup> cells from the responder N.Y. increased from 31% for the resting cells to 68% on day 23 after activation; cells from responder A.A. increased from 20% to 51% and R.H. from 17% to 71%. It was then important to establish if the expanded TH<sup>+</sup> population also expressed the Ia antigens. The activated and resting cells were tested with two fluorescent labels for the simultaneous expression of Ia and TH2 (see Table 4). On day 11, 41 out of 45 (91%) R.H. TH2 T cells expressed the Ia antigen, compared with 12 out of 41 'day 7' A.A. cells (28%).

In another series of experiments, 7- and 23-day activated cells were separated into Ia<sup>+</sup> and Ia<sup>-</sup> by means of a fluorescence activated cell sorter (FACS-1) with an anti HLA-DR (non-polymorphic) monoclonal antibody (DA2). The 7-day unseparated population contained 36% TH2<sup>+</sup> cells and 12% Ia<sup>+</sup>. When separated into subpopulations, the Ia<sup>+</sup> cells were

PBL from donors R.H., J.A. and V.A. were stimulated in culture ( $1 \times 10^6$  cells per ml) with 1:100 final dilution of PHA for 36 h. The supernatant (conditioned medium, CM) was decanted and the cells resuspended in fresh medium (RPMI 1640 plus 10% AB serum) containing 30% CM (v/v final dilution). The cultures were maintained for up to 30 days by changing the medium with CM every 3-4 days. The suppressor effect of the activated T cells (>95% E-rosetting positive cells) on the response of resting cells to PPD was studied as follows: At 3, 8, 11 and 18 days after PHA activation,  $5 \times 10^4$  activated cells in 50  $\mu$ l of medium (without CM) were irradiated with 4,000 rad and mixed with  $5 \times 10^4$  syngeneic resting lymphocytes (50  $\mu$ l) in the presence or absence of 0.6  $\mu$ g of PPD (50  $\mu$ l). As a control,  $5 \times 10^4$  resting cells were mixed with an equal number of syngeneic irradiated resting cells, in the presence or absence of PPD. Kinetic studies of DNA synthesis measured by the addition of  $^3$ H-thymidine between days 3 and 6 showed that the peak of incorporation of isotope was on day 4.5.  $^3$ H-thymidine uptake was measured on day 4.5 and percentage inhibition calculated as follows:

$$1 - \frac{\text{c.p.m. SAC(with PPD)} - \text{c.p.m. SAC(without PPD)}}{\text{c.p.m. resting cells(with PPD)} - \text{c.p.m. resting cells(without PPD)}} \times 100$$

50  $\mu$ l of autologous PBL ( $5 \times 10^4$ ) were cultured in quadruplicate on microtitre V-well plates in RPMI 1640 plus 10% AB serum, then  $2 \times 10^4$  irradiated autologous normal PBL or '23 day' activated cells were added in 50  $\mu$ l of the same medium.  $5 \times 10^4$  allogeneic cells were added to each well of this mixture. For each experiment, the cultures were pulsed for 16 h with 1  $\mu$ Ci of  $^3$ H-thymidine after 2, 3, 4 and 5 days of culture, and results expressed in c.p.m. on the peak stimulation on day 5.5.

\* Irradiated.

† HLA phenotype = A3,A11/B12,B35/DR2,DR4.

48% and the Ia<sup>-</sup> cells were 32% TH2<sup>+</sup>. The 23-day activated population contained >90% Ia<sup>+</sup> TH2<sup>+</sup> cells.

Subsequently, the populations (Ia<sup>+</sup> and Ia<sup>-</sup>) from 7- and 23-day activated cells were assayed for suppressor properties. With 23-day activated cells, most of the suppressor effect was confined to the Ia<sup>+</sup> population (Fig. 1). However, when irradiated Ia<sup>+</sup> or Ia<sup>-</sup> 7-day activated cells were added to syngeneic responders and stimulated by a third party, both Ia<sup>+</sup> and Ia<sup>-</sup> cells stimulated strongly compared with controls (the cultures were assayed on day 4.5). These results suggest a carry-over of PHA although a helper effect of the activating cells cannot be ruled out completely, especially since 50% of the Ia<sup>+</sup> population is not TH2<sup>+</sup>. Because both Ia<sup>+</sup> and Ia<sup>-</sup> populations were stimulators, no conclusions can be drawn about the relative suppressor properties of the various cell subpopulations in these 7-day cultures.

**Table 3** Kinetic expression of TH2 and Ia antigens on activated T cells

| Donor | Days after activation | TH2 | Anti-Ia |
|-------|-----------------------|-----|---------|
| N.Y.  | 0                     | 31% | 17%     |
|       | 14                    | 50% | 42%     |
|       | 22                    | 68% | 65%     |
| A.A.  | 0                     | 20% | 15%     |
|       | 7                     | 42% | 16%     |
|       | 14                    | 45% | 48%     |
|       | 22                    | 48% | 51%     |
| R.H.  | 0                     | 17% | 28%     |
|       | 4                     | 30% | <1%     |
|       | 9                     | 40% | 42%     |
|       | 14                    | 55% | 51%     |
|       | 22                    | 71% | 83%     |

Indirect immunofluorescence was used to analyse cell surface markers. Resting or activated cells ( $1 \times 10^6$ ) were treated with 1:50 (final dilution) of horse anti-human TH2 and with two anti-Ia McAB (DA2 and 62-3-34, both mouse anti HLA-DR non-polymorphic antibodies) at 1:25 (final dilution). The TH2 antibody was obtained from G. Janosy who prepared it from a batch of ATG (lot no. 17923, Upjohn) which was originally shown to have anti TH2 activity, and purified it according to the method of Reinherz and Schlossman<sup>8</sup>. The specificity was validated by comparing the prepared antibody with the Reinherz and Schlossman antibody on lymphocytes from a panel of 26 unrelated individuals and the reactions of the two antibodies were in complete agreement. After 20 min of incubation, 1:25 swan anti-horse FITC-labelled or 1:10 goat anti-mouse rhodamine conjugate antibodies were added to the second layer. Observations were made using a standard 14 Zeiss photomicroscope with epi-illumination (iv F1 epi-fluorescence condenser) and 2F1 reflector sleeve, equipped with exciter and barrier filters, for selective excitation and observation of fluorescence and rhodamine.

The changing antigenic profile of the activated T lymphocytes from Ia<sup>-</sup> into Ia<sup>+</sup> in a population of TH2<sup>+</sup> cells is in sharp contrast to the profile of the resting population, in which there are less than 1% of TH2<sup>+</sup> cells which are also Ia<sup>+</sup>. This implies either that this small sub-population had been expanded over 7 days of culture, or alternatively that the TH2<sup>+</sup> Ia<sup>-</sup> population, already expanded on day 4, became Ia<sup>+</sup> after 8 days of culture. These data strongly suggest that cells with this phenotype are the active suppressors, although there is no direct evidence for this. Ideally one would like to be able to separate the cells into Ia<sup>+</sup> TH2<sup>+</sup> and Ia<sup>-</sup> TH2<sup>+</sup> cells, but the 23-day cells are practically all Ia<sup>+</sup>, whereas the 7-day cultures are all stimulatory, therefore such experiments are uninformative.

These findings may also have functional implications and may be important in the pathogenesis of certain diseases. For example, the increase of the Ia<sup>+</sup> T cells *in vivo* could reflect the efforts

of the immune system to control the autoimmune reaction, for example in rheumatoid arthritis and systemic lupus erythematosus, where a disproportionate increase of Ia<sup>+</sup> T cells in the peripheral blood has been reported<sup>27</sup>. These alloantigens could be central to immunoregulation, and changing proportions of cells carrying one kind of alloantigen or another following stimulation by microorganisms or tumour-associated transplantation antigens may result in the production of suppressor/helper sub-populations.

**Table 4** Simultaneous expression of TH2 and Ia<sup>+</sup> antigens on the surface of PHA-activated cells

| Responder | Days after activation | TH2 <sup>+</sup> | Ia <sup>+</sup> | Ia <sup>+</sup> and TH2 <sup>+</sup> |
|-----------|-----------------------|------------------|-----------------|--------------------------------------|
| A.A.      | 0                     | 20%              | 15%             | 1%                                   |
| A.A.      | 7                     | 42%              | 16%             | 12%                                  |

# Monoclonal antibodies which distinguish between human NK cells and cytotoxic T lymphocytes

Joyce M. Zarling

Although it is widely accepted that T cells have a major role in specific tumour immunity, there is now much evidence that natural killer (NK) cells, which exist in many species and spontaneously lyse certain tumour cells *in vitro*, provide early resistance against tumour growth<sup>1-4</sup>. Human NK-cell activity can be augmented *in vitro* by interferon<sup>5-7</sup> and its inducers, including polyinosinic:polycytidylic acid (poly I:C)<sup>8</sup>; furthermore, NK-like activity is generated in mixed leukocyte cultures (MLCs) as is specific cytotoxic T-cell (T<sub>c</sub>) activity<sup>9-11</sup>. When effector cells generated in human MLCs lyse allogeneic or autologous virus-transformed or tumour cells<sup>9-13</sup>, it has been difficult to evaluate the relative contributions of T<sub>c</sub> and NK-like cells to the lysis because the latter, like T cells, can form rosettes with sheep erythrocytes<sup>14</sup> and react with xenogeneic anti-human thymocyte serum<sup>15</sup>. We report here that monoclonal antibodies against human mononuclear cell subpopulations can distinguish T<sub>c</sub> from NK and NK-like cells. OKT3 or OKT8 monoclonal antibodies (reactive with virtually all or a subset of T cells, respectively<sup>16,17</sup>) with complement (C') ablate MLC-generated T<sub>c</sub> activity against allogeneic normal cells but do not decrease lysis of HLA-negative, NK-sensitive K562 leukaemia cells by NK, poly I:C-activated NK or MLC-activated NK-like cells. In contrast, OKM1 monoclonal antibody (reactive with a low proportion of non-adherent mononuclear cells as well as macrophages<sup>18</sup>) with C' causes marked diminution of NK and poly I:C-activated NK-cell activity.

The production and characterization of the monoclonal antibodies used in this study have been reported elsewhere<sup>16-19</sup>; all are ascites fluid preparations from mice inoculated with hybridoma cells producing antibodies of the IgG2 subclass, which fix rabbit C'. However, it had not been determined which, if any, of the antibodies with C' would eliminate cytotoxic effector cells. Thus, peripheral blood mononuclear cells, stimulated in MLC for 7 days with X-ray irradiated normal cells pooled from 20 unrelated individuals (pool<sub>x</sub>), were treated with anti-human T-cell antibodies OKT3, OKT8, OKT4 or control ascites fluid, followed by the addition of C', as detailed in Table 1 legend. Cytotoxic activities of the treated effector cell populations were compared against <sup>51</sup>Cr-labelled allogeneic normal lymphocyte targets which are lysed by T<sub>c</sub> but not by fresh or activated NK cells<sup>7</sup>. Typical results of one of five experiments, shown in Table 1, indicate that treatment of MLC-generated effector cells with OKT3 or OKT8 and C' totally ablated T<sub>c</sub> activity against the normal allogeneic cells. OKT4 and C' did not decrease T<sub>c</sub> activity; however, it is unclear why enrichment of cytotoxicity was not observed following removal of the 33% cells killed by this antibody, because previous results, obtained using the fluorescence-activated cell sorter, showed that OKT4 reacts with a subset of T cells lacking T<sub>c</sub> activity<sup>19</sup>.

Experiments were carried out to determine whether the monoclonal anti-T-cell antibodies would decrease either non-augmented or poly I:C-augmented NK-cell activity against

NK-sensitive K562 cells. Representative results (Fig. 1) confirm our previous report<sup>8</sup> that poly I:C augments human NK-cell activity against K562 cells by approximately 2.5-fold (44.6 lytic units (LU) compared with 106 LU). Exposure of untreated or poly I:C-treated non-adherent mononuclear cells to OKT3 or OKT8 and C', which deplete T<sub>c</sub> activity, did not decrease NK or poly I:C-augmented NK activity against K562 cells in this or in two similar experiments; additionally, OKT4 and C' failed to decrease NK-cell activity. The increase in lytic units per 10<sup>6</sup> cells, following treatment with the anti-T-cell antibodies and C', can be accounted for primarily by enrichment for NK cells resulting from lysis of T cells; this is because the total LU recovered following antibody or control ascites treatments were similar, except for the less than twofold increase in LU recovered following treatment of poly I:C-activated cells with OKT3 and C' (Fig. 1b). In contrast, OKM1 and C' (which lysed 11-14% of the cells) reduced NK and poly I:C-augmented NK-cell activity against K562 cells by at least 75% in this and in two other experiments. It thus seems that the majority of NK and poly I:C-activated NK cells are OKM1<sup>+</sup> and OKT3<sup>+</sup>.

**Table 1** Depletion of MLC-generated T<sub>c</sub> against allogeneic normal cells by monoclonal antibodies OKT3 and OKT8

| Treatment of A pool <sub>x</sub> effector cells | % Specific <sup>51</sup> Cr release from B ± s.d. |            |
|---|---|------------|
|   | 30:1  | 10:1       |
| Control ascites + C'                            | 56.8 ± 8.9  | 38.7 ± 7.5 |
| OKT4 + C'                                       | 50.7 ± 8.4  | 37.2 ± 4.8 |
| OKT8 + C'                                       | 3.7 ± 3.9   | 2.7 ± 3.6  |
| OKT3 + C'                                       | 7.0 ± 4.3   | 5.6 ± 4.0  |

Ficoll-Hypaque-isolated mononuclear cells from individual A were washed and resuspended in culture medium consisting of RPMI 1640 (Gibco) supplemented with 25 mM HEPES buffer and 15% heat-inactivated normal human serum. 9 × 10<sup>6</sup> responding cells from individual A were incubated in a final volume of 10 ml culture medium in Falcon T25 tissue culture flasks with 9 × 10<sup>6</sup> X-ray irradiated (2,500R) allogeneic normal lymphocytes, pooled in equal numbers from 20 unrelated individuals (pool<sub>x</sub>) as previously described<sup>12</sup>. On day 7 after the onset of MLC, the non-adherent A pool<sub>x</sub> effector cells were collected from flasks, washed once and treated in culture medium with control ascites from mice inoculated with the parental myeloma cell line or ascites fluid containing monoclonal antibodies OKT4, OKT8 or OKT3 (produced as described elsewhere<sup>16-19</sup>), at a final dilution of 1:100 for 1 h at 4 °C. Rabbit complement (C') (Pel-Freez Biologicals) was added at a final dilution of 1:2. Following a 1-h incubation at 37 °C, the % viable cells, determined by trypan blue dye exclusion, was 98, 67, 57 and 26% for cells treated with control ascites, OKT4, OKT8 and OKT3, respectively. The treated cells were layered on Ficoll-Hypaque gradients to remove dead cells and the viable cells isolated from the interfaces were washed and resuspended in complete medium before their use as effector cells. Effector cells were added to round-bottom wells of microtitre trays (0.8-2.4 × 10<sup>5</sup> per well) followed by the addition to each well of 8 × 10<sup>3</sup> <sup>51</sup>Cr-labelled allogeneic normal lymphocytes from individual B; the resulting effector to target cell ratios were 30:1 and 10:1. Following a 7-h <sup>51</sup>Cr-release assay at 37 °C, a constant amount of supernatant was removed from each well and transferred to tubes for counting in a γ-counter. The % specific <sup>51</sup>Cr release from target cells was calculated as follows:

$$\frac{(\text{c.p.m. test release} - \text{c.p.m. spontaneous release})}{(\text{c.p.m. maximal release} - \text{c.p.m. spontaneous release})} \times 100$$

where spontaneous release = c.p.m. release from target cells in medium alone, and maximal release = c.p.m. release from target cells in detergent. Spontaneous <sup>51</sup>Cr release was 13.2% of the maximal release. The values shown are the mean specific % <sup>51</sup>Cr released from four replicate wells ± s.d. The % specific <sup>51</sup>Cr released from the cells by mononuclear cells from individual A cultured for 7 days without stimulating cells was 4.2 ± 1.3%. The % specific <sup>51</sup>Cr released from the target cells by A pool<sub>x</sub> effector cells treated with control ascites and C', control ascites alone, C' alone or antibodies in the absence of C' did not differ from that released by untreated effector cells.

OKT4<sup>+</sup> and OKT8<sup>+</sup>. This finding firmly supports a recent hypothesis that NK cells might be OKM1<sup>+</sup>, which was based on data showing that OKM1 antibody reacts in immunofluorescence assays with the majority of non-adherent cells having surface characteristics of NK cells<sup>20</sup>, that is, receptors for sheep erythrocytes<sup>14</sup> and for the Fc portion of IgG (refs 7, 11, 14). Our failure to ablate NK-cell activity totally by OKM1 and C' (Fig. 1) suggests that either a small percentage of NK cells are OKM1 or that they express a very low density of OKM1 antigen.

Effector cells generated in MLC can lyse certain allogeneic and autologous lymphoblastoid cell lines and leukaemia

**Fig. 1** Effect of monoclonal antibodies on NK and poly I:C-augmented NK-cell activities.  $10 \times 10^6$  Ficoll-Hypaque isolated mononuclear cells were cultured in Falcon T25 tissue cultured flasks containing 5 ml RPMI 1640 medium supplemented with 25 mM HEPES buffer, 15% normal human serum and 0 (a) or 100  $\mu$ g (b) poly I:C ml $^{-1}$ . Following a 16-h incubation at 37°C, the non-adherent cells (containing <1% macrophages, as judged by nonspecific esterase staining) were collected and treated with antibodies or control ascites and C' as detailed in Table 1; OKM1 was used at a dilution of 1:10. The numbers of viable cells recovered after treating  $10^7$  cells with OKT3, OKT8, OKT4, control ascites or OKM1 and C' were 3.0, 5.0, 6.2, 9.3 or  $8.2 \times 10^6$ , respectively (a), and 3.1, 3.6, 5.3, 9.3 or  $8.5 \times 10^6$ , respectively (b). The washed effector cell populations were tested for cytotoxicity against  $^{51}$ Cr-labelled K562 cells in a 5-h  $^{51}$ Cr release assay. The data points represent the mean % specific  $^{51}$ Cr released from K562 cells in four replicate wells, calculated as in Table 1; the s.d. values were <12% of the mean values. Spontaneous  $^{51}$ Cr release was 11.2% of maximal release. 1 LU (lytic unit) was defined as the number of effector cells required to cause 35% specific  $^{51}$ Cr release from  $8 \times 10^3$  target cells. Total LU recovered after treating  $10^7$  cells was calculated as follows: LU per  $10^6$  cells  $\times$  no. of viable cells recovered.

cells<sup>9-13</sup>, which may be sensitive to lysis by NK or activated NK cells<sup>7</sup>. It is difficult to determine the proportion of such cytotoxicity that is mediated by T<sub>c</sub> or NK-like cells; the mere observation that NK-sensitive target cells are lysed is insufficient to exclude participation by T<sub>c</sub> in the lytic reaction. In attempts to distinguish T<sub>c</sub> from NK-like cells, effector cells generated in MLC by stimulation with pooled allogeneic normal cells, were treated with OKT3 or OKT8 and C' and were then tested for their ability to lyse allogeneic normal lymphocytes and HLA-negative K562 cells. Results shown in Fig. 2a, similar to those shown in Table 1, indicate that OKT3 or OKT8 plus C' depletes T<sub>c</sub> activity against allogeneic normal lymphocytes; in contrast, treatment of the stimulated cells with OKT3 or OKT8 and C' did not decrease cytotoxicity against the NK-sensitive K562 leukaemia cells (Fig. 2b). Similar results were obtained in four other experiments; however, the total LU recovered against K562 cells from OKT3-treated cells was not consistently higher than that recovered from control ascites-treated cells. Our results thus demonstrate that T<sub>c</sub> can be distinguished from MLC-activated NK-like cells by use of monoclonal OKT3 or OKT8 antibodies and C'.

Although we observed that OKM1 plus C' caused marked diminution of fresh and poly I:C-activated NK cells (Fig. 1), we have failed, with such a treatment, to eliminate cytotoxic activity of effector cells generated in MLC against allogeneic normal cells or K562 cells (data not shown). This finding is reminiscent of observations that NK as well as interferon- and poly I:C-augmented NK-cell activities are depleted by removing cells expressing receptors for the Fc portion of IgG (refs 7, 8, 11, 14); however, both NK-like cells and T<sub>c</sub> generated in MLC seem to lack Fc receptors<sup>11,21</sup>. The relationship between OKM1 antigen and the Fc receptor on NK cells remains to be elucidated. It is possible that MLC-activated NK-like cells are derived from OKM1<sup>+</sup> cells but that following several days in MLCs, the OKM1 antigen may not continue to be expressed on these cells; alternatively, the NK-like cells generated in MLCs may originate from a phenotypically different precursor cell.

As monoclonal antibodies directed against human mononuclear cell subpopulations can distinguish T<sub>c</sub> from NK and NK-like cells, it is now possible to delineate the effector cells that are cytotoxic for a variety of cell lines and autologous malignant cells.

**Fig. 2** Distinction between T<sub>c</sub> and NK-like cells generated in MLC by monoclonal anti-T-cell antibodies. Peripheral blood mononuclear cells were stimulated for 7 days in MLC with X-ray irradiated pooled allogeneic normal cells and collected and treated with monoclonal antibodies OKT3 or OKT8 and C' as detailed in Table 1 legend. The numbers of viable cells recovered after treating  $10^7$  cells with control ascites, OKT3 or OKT8 with C' were 5.7, 1.4 or  $4.4 \times 10^6$ , respectively. The effector cells were then tested for cytotoxicity against allogeneic normal lymphocyte targets (a) and HLA-negative K562 leukaemia cells (b) in 7-h and 5-h  $^{51}$ Cr release assays. The % specific  $^{51}$ Cr released from targets by responding cells cultured in the absence of stimulating cells is designated by  $\Delta$ . Negative % specific  $^{51}$ Cr release values indicate that less  $^{51}$ Cr was released from target cells in the presence of effector cells than that which was released spontaneously in medium alone. Spontaneous  $^{51}$ Cr release from allogeneic normal cells and K562 cells was 14.8 and 10.2% of maximal  $^{51}$ Cr release. LU per  $10^6$  cells and total LU recovered from  $10^7$  cells were calculated as shown in Fig. 1. One lytic unit was defined as the number of effector cells required to cause 15% or 40% specific  $^{51}$ Cr release from  $8 \times 10^3$  labelled allogeneic normal cells or K562 cells, respectively.

We thank Ms M. S. Dierckins and Ms M. Cunanan for assistance and Dr G. Goldstein for valuable discussions. This work was supported by NIH grant CA26738 and a grant from the Minnesota Medical Foundation to J.M.Z. who is a Scholar of Leukemia Society of America.

## H-2-linked genes control immune response to V-domains of myeloma protein 315

Trond Jørgensen & Kristian Hannestad

Institute of Medical Biology, University of Tromsø School of Medicine, Tromsø, Norway

**Immunoglobulins function as antigen receptors of B lymphocytes and as effector molecules for elimination of foreign antigens. Recently, other functions have been revealed: for example, idiotypes (antigenic sites of variable (V) domains) bound on the surface of plasmacytomas<sup>1,2</sup> can act as tumour-specific transplantation antigens<sup>3</sup>. Moreover, optimal maturation of B lymphocytes of a given idio type into antibody-secreting cells seems to require assistance from two different kinds of helper T cells (Th), one bearing receptors complementary or similar to that idio type, and another that recognizes the antigen<sup>4-6</sup>. To learn more about recognition of V regions by Th, we have used V-domains of the immunoglobulin A (IgA) (A2) myeloma protein M315 produced by the BALB/c plasmacytoma MOPC 315 (ref. 7) as carriers for anti-hapten responses. We report here that the Th response to the V-domain of the heavy chain (V<sub>H</sub>) and the light chain (V<sub>L</sub>) of M315 seems to be under H-2-linked immune response (IR) gene control.**

Varibus strains of mice were injected separately with 100 µg of V<sub>H</sub><sup>315</sup> and V<sub>L</sub><sup>315</sup> (carrier) and 200 µg of hapten coupled to bovine serum albumin (BSA). The hapten was the (4-hydroxy-5-iodo-3-nitrophenyl)acetyl (NIP) group. The Th responses to the two carrier antigens were determined by transferring the carrier-primed spleen cells to irradiated (500R X-ray) syngeneic recipients together with hapten-primed B cells. We concluded that those strains in which a pronounced anti-NIP response was observed 10-12 days following boost with 200 µg of NIP<sub>3</sub>-Fab<sup>315</sup> in saline had responder Th, whereas those strains in which the anti-NIP response was very low had non-responding Th. Previous studies had established that the BALB/c anti-NIP antibody response in this adoptive transfer system is Th dependent<sup>8,9</sup>. For example, BALB/c spleen cells primed with minimal essential medium (MEM) or BSA have never evoked a secondary anti-NIP response above 7.5% (see Table 1).

This analysis revealed that for each antigen the various mouse strains could be clearly distinguished into high responders and non-responders (Table 1). Thus, mice of the d (BALB/c and DBA/2), b (C57BL) and s (SJA, SJL) haplotypes made strong anti-NIP antibody responses when they received Th primed with V<sub>L</sub><sup>315</sup>. Mice of the k (CBA, C3H and AKR) haplotype made no or poor anti-NIP responses. For unknown reasons, CBA mice from Gl. Bomholtgaard gave a higher response to V<sub>L</sub> than the other H-2<sup>k</sup> strains (Table 1, expt A), including CBA from the Jackson Laboratory (Table 1, expt B).

A different genetic pattern was observed for Th responses to V<sub>H</sub><sup>315</sup>. Mice of the k and s haplotypes made strong anti-NIP responses, whereas mice of the b and d haplotypes made no or weak responses (Table 1). The Th of (C3H × BALB/c)F<sub>1</sub> mice responded to both V<sub>H</sub> and V<sub>L</sub> priming (Table 1), showing that the responder phenotypes are inherited in a dominant fashion.

Mice of the b (C57BL/6), d(BALB/c) and k (C3H, CBA, AKR) haplotypes were also primed with the Fv fragment of M315 which contains both the V<sub>H</sub> and the V<sub>L</sub> domains. In contrast to the distinct response patterns observed with the isolated V-domains, all strains were responders to Fv (Table 1, expt C). We have been unable to demonstrate suppressor activity in spleen cells of V<sub>H</sub><sup>315</sup>-primed BALB/c mice. Thus, the anti-NIP responses of recipients that received a mixture of 20 × 10<sup>6</sup> V<sub>L</sub>- and 80 × 10<sup>6</sup> V<sub>H</sub>-primed spleen cells were equivalent to the responses of animals receiving only V<sub>L</sub>-primed cells (data not shown).

The importance of the major histocompatibility complex (MHC) genes in these responses is shown by the correlation between MHC type and ability to respond to either V<sub>H</sub> or V<sub>L</sub> (Table 1). Furthermore, the congenic strain BALB.K (H-2<sup>k</sup>), which only differs from BALB/c at the H-2 complex, responds like mice of the k haplotype (Table 2). Thus, it is a non-responder to V<sub>L</sub><sup>315</sup>, although BALB/c responds, and it is a responder to V<sub>H</sub><sup>315</sup>, although BALB/c does not respond. There was no correlation between Igh-C allotypes and response patterns (Table 1). These results provide strong evidence that distinct genes within the MHC control the Th responses to these V-domains.

What is the nature of the V-domain epitopes recognized by the Th of this study? The genetic background of the mouse in which MOPC-315 arose was the seventh generation of successive backcrosses to inbred BALB/c mice, starting with the F<sub>1</sub> progeny of a BALB/c × C57BL/Ka cross. The progeny selected for each backcross with BALB/c had both BALB/c and C57BL/Ka allotypic Igh-C markers<sup>10</sup>. As M315 bears the same Igh-C allotypes (A<sup>12,13,14</sup>) as BALB/c IgA myeloma proteins<sup>7</sup>, the BALB/c origin of C<sub>H</sub><sup>315</sup> is established. It has not been possible to prove the BALB/c origin of L<sup>315</sup> because no allotypic markers have been found on the λ2 chain. However, the probability that L<sup>315</sup> is the product of C57BL genes is only 1/256 (ref. 10). As both BALB/c and C57BL mice have on average 11-14 µg per ml of protein immunochemically related to V<sub>L</sub><sup>315</sup> (ref. 11) and are responders to V<sub>L</sub><sup>315</sup> (this work), it is unlikely that the antigenic determinant is an allotype. Hence we conclude that it is related to idiotypes. For V<sub>H</sub><sup>315</sup> one cannot rule out allotype as both BALB/c and C57BL are non-responders.

These experiments demonstrate that complete immunoglobulins may be unsuitable for priming Th in studies of MHC-linked IR gene control of immune responses to V-regions because complete immunoglobulins may, as with M315, bear more than one genetically controlled V-region determinant. This is illustrated by the uniform high responsiveness of all strains to the Fv-315 fragment. In addition, new epitopes formed when V<sub>H</sub> and V<sub>L</sub> are assembled, as in Fv, may also contribute to these high responses. Therefore, the lesser antigenic complexity of individual domains offers certain advantages in the dissection of the immunogenicity of complete immunoglobulins. Second, a significant set of Th present in many mouse strains recognize the V-domains of M315 in another way than most B lymphocytes. Thus, the anti-idiotypic antibodies raised in isogenic mice against M315 usually bind to

**Table 1** Separate genetic control of helper T-cell (Th) responses to  $V_H^{315}$  and  $V_L^{315}$

| SJL                  | s           | b             | 45.5 (5.2)   | 66.4 (2.0) | 50.1 (3.7)      | 54.9 (5.5)   |
| SJA                  | s           | a             | 26.1 (3.3)   | 43.2 (4.3) |                 |              |

Each irradiated (500R X ray) recipient was given  $\frac{1}{2}$  spleen equivalent of NIP-BSA- and carrier-primed cells<sup>9</sup>. The values represent per cent of  $1.2 \times 10^{-6}$  mol of N-[<sup>125</sup>I]P-caproic acid bound by 20  $\mu$ l serum collected 10 days (expts A and B) and 13 days (expt C) after boost with NIP<sub>3</sub>-Fab<sup>315</sup>. BALB/c spleen cells primed with MEM or BSA have never evoked a secondary anti-NIP response above 7.5% in this assay system. The numbers in parentheses are s.e.

\* Mice of expts A and C were from Gl. Bomholtgaard, and of expt B from the Jackson Laboratory. The SJA strain was from Institute of Cancer Research, Philadelphia.

<sup>†</sup> C57BL/6 in expts A and C; C57BL/10 in expt B.

'neo' antigenic idiotype determinants that form when the  $V_H$  and  $V_L$  domains assemble<sup>12</sup>. We propose that the Th primed with individual  $V^{315}$  domains encounter and recognize the same domains in an assembled form when the animals are boosted with NIP<sub>3</sub>-Fab<sup>315</sup>, and that these Th focus on immunogenic sites shared by free and assembled V-regions. According to this hypothesis each member of the M315 pair of V-domains contains sufficient structural information by itself to be recognized by Th. This interpretation is in line with Edelman's proposal that each of the compact domains of immunoglobulin chains has evolved to perform a special function<sup>13</sup>, and contrasts with the combined contribution of  $V_H$  and  $V_L$  domains to the construction of the antigen-binding sites of complete antibodies<sup>14,15</sup> and many, but not all, serologically defined idiotypes.

The broader implications for the idiomotype network<sup>16</sup> concept are that the V-region-specific Th of the present study, detected by a conventional hapten-carrier system, may be envisaged to be able to operate directly on the immunoglobulin receptors of B lymphocytes like the idiomotype-specific set of Th (refs 4–6). Hence,  $V_H$  and  $V_L$  may also function as independent targets in the idiomotype network and the same Th may be able to perform both carrier- and idiomotype-specific help.

An objection to this interpretation is that the immunoglobulin receptors of B cells presumably are not subject to antigen processing before recognition by idiomotype-specific Th whereas such processing may have taken place with the antigens of the present study. Evidence against this objection derives from an earlier experiment where  $L^{315}$  priming of Th from BALB/c mice not only augmented the anti-NIP responses but also the antibody responses to the M315 idiomotype of recipients boosted with M315 (ref. 8). As the serologically defined idiomotype of M315 requires assembled ( $V_H + V_L$ ) domains for its expression, and as the determinants recognized by collaborating B and Th cells must be present on the same molecular complex<sup>17</sup>, this result suggests that the V-domains of M315 used in the present

experiments were recognized as intact during priming and assembled during the boost.

This work was supported by the Norwegian Research Council for Science and the Humanities, the Norwegian Cancer Society and the Norwegian Society for Fighting Cancer.

**While studying the plasma membrane of sperm of the sea urchin *Strongylocentrotus purpuratus*, we developed an antiserum that exhibits unusual reactivity—it cross-reacts with the surfaces of spermatozoa of 28 species representing seven phyla of the animal kingdom. A negative cross-reaction has not been found. This suggests the possible existence of common antigenic determinants on the surface of all animal sperm. We report these preliminary results here because of the broad implications common sperm-surface antigenicity has for the potential development of immunocontraceptive methods.**

\* The strains BALB/c and C3H were purchased from Gl. Bomholtgaard. BALB/K mice were from Olac 1976.

<sup>†</sup> Values expressed as in Table 1. The serum was collected 11 days after boost with NIP<sub>3</sub>-Fab<sup>315</sup>.

**Fig. 1** Cross-reactivity of SSA with sperm of four species visualized by the immunoperoxidase procedure. Approximately equal numbers of spermatozoa ( $5 \times 10^8 \text{ ml}^{-1}$ ) were used for each reaction (tube on left, SSA; tube on right, preimmune serum). a, *S. purpuratus* (sea urchin); b, *Rattus norvegicus* (rat); c, *Salmo* sp. (salmon); d, *Metridium senile* (*fibriatum*) (sea anemone). To prepare SSA, sperm of the sea urchin *S. purpuratus* were washed by sedimentation (1,000 g, 10 min) in filtered sea water to remove seminal fluid, fixed 1 h in 3% glutaraldehyde-sea water, then washed to remove the fixative. They were resuspended in phosphate-buffered saline (PBS, pH 7.2, 0.5 mg per ml sperm protein), mixed with Freund's complete adjuvant (1 Freund's: 2 sperm) and a virgin female New Zealand rabbit was immunized by direct injection into the popliteal lymph nodes<sup>14</sup>. After 4 weeks a second injection was given subcutaneously and the rabbit bled 10 days later. Serum was removed following clot retraction and heated to 56 °C for 30 min. To eliminate non-sperm-specific activities, antiserum was absorbed with minced sea urchin ovary and non-gametic male tissues (coelomocytes and tube feet) by incubating the tissues in antiserum, then clarifying by centrifugation. To obtain a 1% TX-100 extract, sperm were washed and resuspended in sea water containing 10 mM TAME (*p*-tosyl-1-arginine-methyl ester) and 10% TX-100 in sea water added to a final concentration of 1%. After 30 min the soluble extract was collected by centrifugation at 30,000 g for 30 min. To perform the immunoperoxidase localization, sperm were fixed for 1 h in 3% glutaraldehyde- or formaldehyde-sea water (or PBS), washed and then incubated for 30 min in 10% normal swine serum (NSS). Following removal of excess NSS, the cells were incubated 1 h in preimmune serum (1/80) or SSA (1/80), washed three times in 1% NSS-PBS, incubated 15 min in horseradish peroxidase-conjugated swine anti-rabbit IgG (1/50; Bio-Rad Laboratories) and washed three times in 1% NSS-PBS over a 12-h period. The cells were then resuspended in 1 ml reaction mixture, containing 0.75 mg Hanks-Yates reagent (Polysciences), 0.1 M Tris-HCl, pH 7.6, and 0.01%  $\text{H}_2\text{O}_2$  (ref. 15). After 15 min the cells were washed in PBS, transferred to a clean tube and the presence or absence of reaction product determined by direct visual observation or phase-contrast microscopic observation of the cell suspension. The precipitate was visible over the entire cell surface. No free precipitate was observed in the suspension. Preimmune serum did not react. Hanks-Yates reagent was used in place of diaminobenzidine because the latter is a potent carcinogen.

The antiserum was prepared using whole, glutaraldehyde-fixed *S. purpuratus* sperm as the immunogen. Fixed cells may be a better immunogen than their unfixed counterparts because they are not cleared by macrophages as readily as unfixed ones, thus creating an artificial booster effect<sup>1</sup>. The antiserum to the fixed sperm produced several precipitin lines when diffused in agar against a Triton X-100 (TX-100) extract of sea urchin sperm. Following absorption of the whole antiserum with sea urchin ovary and non-gametic male tissues, only one precipitin line appeared in the agar plate. However, we recognize that minor antigenic activities may remain undetected by simple immunodiffusion assay (the number of antigenicities present in the absorbed serum is not the point of this letter). This absorbed antiserum is hereafter designated 'sperm-specific antiserum' (SSA). The sperm-specific activity of SSA could be completely eliminated by absorption with fixed or living sperm [as determined by immunodiffusion, immunoperoxidase and indirect immunofluorescence (IIF)]. The SSA inhibited the egg jelly-induced acrosome reaction in living *S. purpuratus* sperm.

When the SSA was tested for cross-reactivity (using immunoperoxidase and IIF) with sperm of other species, we found that every species gave a positive reaction (Figs 1 and 2, Table 1). Rat sperm (Figs 1b and 2d), salmon sperm (Fig. 1c) and coelenterate sperm (Fig. 1d) reacted as strongly as sea urchin sperm (Figs 1a and 2b). We stress that this is a qualitative assay and that we have not determined the number of binding sites for the SSA on a per cell basis. The results obtained with IIF (Fig. 2) and phase-contrast and bright-field observations of immunoperoxidase-reacted cells showed that the activity is distributed over the entire surface of the sperm. Controls on the immunoperoxidase procedure (Fig. 3) showed that the deposition of the coloured reaction product depended on the reaction of the SSA with the sperm surface. A variety of cell types were tested to determine that the activity was indeed sperm specific; no non-sperm cell types reacted with the SSA (Table 2).

The unusual reactivity of this antiserum led us to perform an extensive series of controls to establish that the sperm-specific activity was not artefact. Because glutaraldehyde-fixed sperm were used as the immunogen, we examined whether the activity of the SSA might be due to a glutaraldehyde-hapten effect. This has been ruled out by the following findings: (1) The SSA raised against the glutaraldehyde-fixed sea urchin sperm reacted with both living sperm and formaldehyde-fixed sperm. (2) Another antiserum, raised by injecting unfixed, whole sea urchin sperm into a rabbit, had the same reactivity as the serum to glutaraldehyde-fixed sperm. (3) A third antiserum produced by

using a 1% TX-100 extract of sea urchin sperm as the immunogen also had the same specificity. (4) The activity of the SSA was completely eliminated by absorbing the antiserum with either living or glutaraldehyde-fixed sperm, also showing that the activity was directed against surface molecules.

Because there are carbohydrate sequences in complete Freund's adjuvant that might elicit the production of antibodies that cross-react with some mammalian sperm<sup>2</sup>, two experiments were performed to show that the activity of the SSA was not the result of this phenomenon. First, a rabbit was injected with complete Freund's adjuvant only from the same vial of adjuvant that had been used in production of the SSA. Both the pre-injection and post-injection sera from this rabbit showed no reactivity with sperm. Second, a rabbit was immunized with

Reactivity of the SSA was assayed by IIF or by the immunoperoxidase procedure. The sperm were fixed in either 3% glutaraldehyde or formaldehyde. Preimmune serum did not react. See Figs 1 and 2 legends for methods.

**Fig. 2** Reactivity of SSA with sperm of three species visualized by IIF *a* and *b*, sea urchin; *c* and *d*, rat; *e* and *f*, turkey. *a*, *c* and *e*, preimmune serum; *b*, *d* and *f*, SSA. Sperm were fixed and washed as in Fig. 1 legend, then incubated for 1 h in preimmune serum (1/100) or SSA (1/100), washed three times in 1% normal rabbit serum in PBS, incubated 15 min in 1:10 fluorescent goat anti-rabbit antiserum (Antibodies Incorporated), and washed three times in PBS over a 30-min period. The cells were then resuspended in PBS and observed and photographed on GAF 500 film with a Zeiss fluorescent microscope equipped with an Osram mercury lamp. The fluorescence appears over the entire cell surface. Pre-immune serum did not react.

unfixed sperm without adjuvant, and this antiserum, after absorption, had the same specific reactivity as the SSA.

The possibility existed that the supposedly sperm-specific activity was not due to the recognition of a surface antigen but resulted from the cross-reactivity of male accessory gland secretions. However, no reactivity was detected when sea urchin seminal fluid was diffused in agar against the SSA. Another possibility was that the SSA was recognizing H-Y antigen, the male sex-determining antigen present on the sperm (and all other cells) of all species in which the male is the heterogametic sex<sup>3,4</sup>. To answer this question the following experiments were performed. First, the serum was extensively absorbed using sea urchin male non-gametic tissues (coelomocytes and tube feet); the activity of the SSA was not affected. Second, the antiserum

was extensively absorbed using splenocytes from two male rats (the standard procedure for absorbing H-Y antibodies<sup>5</sup>); there was no loss of activity of the SSA. It has been reported that H-Y activity is limited in distribution to the region of the acrosomal cap in mammalian sperm<sup>6</sup>. We found, however, that SSA activity was distributed over the entire surface of rat and hamster sperm, as judged by immunoperoxidase localization using phase-contrast microscopy at  $\times 1,000$  magnification and by IIF. Finally, the serum reacted with turkey sperm by both the immunoperoxidase and IIF (Fig. 2*e*, *f*) procedures, proving conclusively that the SSA is not recognizing H-Y activity, because in birds the heterogametic sex, and hence the bearer of H-Y (H-W in birds), is the female<sup>3,4</sup>.

**Fig. 3** No reaction product was deposited when the immunoperoxidase procedure was performed using sea urchin sperm in the absence of one of the following reactants: *a*, hydrogen peroxide; *b*, SSA; *c*, horseradish peroxidase. *d*, Preimmune serum, and *e*, SSA, all reagents included.

In mammals, cross-reacting antigens exist among nervous tissue, sperm and preimplantation embryos<sup>7</sup>. However, we found that the SSA did not react with fixed or unfixed rat brain. Some sperm, such as those of the rabbit, nonspecifically bind the Fc region of antibodies<sup>8</sup>. To exclude this as a possibility for the activity of our SSA, we tested two other antisera raised against two different genus-specific sea urchin sperm surface glycoproteins (*S. purpuratus*<sup>9</sup>). Sperm of 16 species, representing four phyla, did not react with these other antisera, showing that the activity of the SSA did not result from nonspecific binding of the Fc region of the rabbit immunoglobulins. To investigate the possibility that the SSA was reacting with cell-surface tubulin, we reacted it with *Chlamydomonas reinhardtii* cells and mussel gill tissue (*Mytilus californicus*), two cell types reported to have tubulin on their outer surface<sup>10-13</sup>. Both cell types gave a negative reaction by the immunoperoxidase assay. The results here suggest that common cross-reactive antigenic determinant(s) exist which are specific to the surface of animal sperm.

We thank Drs B. S. Dunbar, R. P. Erickson, E. Goldberg, and S. Sarkar for discussions, G. W. Moy for technical assistance, and Drs P. G. Calarco and C. L. Banka for use of the fluorescent microscope and assistance with the immunofluorescence assay. This work was supported by NIH HD 12986 to V.D.V. A.C.L. was a 1977-78 American Association of University Women predoctoral fellow.

## Retroviral antigens on $gs^- chf^-$ leukocytes

It has recently been suggested that the endogenous retroviruses present in many different species might be involved during stimulation of the immune system of their hosts<sup>1-3</sup>. We have now studied the expression of two avian retroviral antigens p27 and gp85 in chicken lymphoid cells by indirect immunofluorescence (IIF) and by complement-dependent microcytotoxicity (CDM). We have now found that these viral antigens are expressed in peripheral blood leukocytes of adults and embryos and in splenic and bursal lymphocytes of Spafas  $gs^- chf^-$  chickens but they are not expressed in fibroblasts cultured from the feather follicles of the same individual adult birds nor in fibroblasts cultured from embryos of the same flock. The differential expression of viral antigens in leukocytes may be related to a specific property or function of these cells.

We wished to study the possible modifications of the expression of avian retroviral antigens by chicken lymphoid cells during the immune response, but, using outbred  $gs^+ chf^+$  birds, we observed that their lymphoid tissues frequently expressed considerable quantities of p27 and gp85 as estimated by IIF (see Table 1). Splenic cells from some 20 birds of ages ranging from 3 weeks to 6 months were 30–100% positive for either antigen; bursal cells from the same birds were more variable, some samples being negative for one or both of the antigens, others consisting of 100% positive cells. Only a few samples of peripheral blood leukocytes from these birds were examined but they were uniformly strongly positive ( $\geq 80\%$ ) for both antigens. These results agree with those of Chen and Hanafusa<sup>4</sup> who used radioimmunoassay techniques to show that p27 was expressed in greater amounts by the lymphocytes of such chickens than by any other tissue. We therefore decided to use Spafas chickens which, although they contain the endogenous viral genome, do not usually express the corresponding antigens<sup>5-7</sup>.

In an initial experiment, leukocytes from peripheral blood of adult Spafas chickens were examined by IIF for expression of viral antigens (see Table 1). A considerable proportion of peripheral blood leukocytes from all four of the birds reacted with the anti-gp85 serum (50–90%) and with the anti-p27 serum (40–70%) and these percentages remained fairly stable for the individual birds over the experimental period. The birds were killed and smears prepared from mechanically disrupted splenic and bursal tissue and compared with the peripheral blood samples. The percentage of positive cells was never higher in these tissues than in the corresponding blood.

These results were confirmed using a CDM assay as described by Mohanakumar *et al.*<sup>8</sup>. A series of Spafas chickens were the source of peripheral blood leukocytes and these were examined by the CDM test using the same antisera as used in the IIF.

In these conditions, the anti-p27 serum caused a specific cytotoxicity of 50–80% of Spafas peripheral blood leukocytes at a dilution of 1:20 and had an end point titre of 80–160. The anti-gp85 serum showed greater reactivity, regularly killing some 90% of the target cells at dilutions up to 1:5,000 and having an end point titre of 20,000–40,000 (Fig. 1). The specificity of this reaction was verified by absorption of the serum against cells with known expression of viral antigens. This

activity could be absorbed by Spafas blood leukocytes or by mammalian cells transformed by Rous sarcoma virus and expressing viral antigens but not by analogous untransformed cells nor by Spafas fibroblasts even after 5-bromodeoxyuridine (BUdR) treatment. Similar results, although at lower titre, were obtained with antisera raised in rabbits using a different preparation of p27 and gp85 antigens.

As a further control, the reactivity of the sera towards Spafas embryo fibroblasts was tested by IIF. Neither p27 nor gp85 was ever expressed over 12 culture passages, even after culturing the cells for 6 days in the presence of BUdR ( $4 \mu\text{g ml}^{-1}$ ). We also cultivated fibroblasts from the feather follicles<sup>9</sup> of individual Spafas chickens which provided the blood leukocytes for comparisons over the culture period. These fibroblasts also showed no reactivity by IIF for either antigen even after BUdR treatment and were incapable of absorbing the reactivity of the sera for leukocytes of the same individual chicken (Fig. 1).

The expression of these antigens by peripheral blood leukocytes has regularly been observed at all ages from newly hatched chicks to birds of over 1 year old. We have also tested some samples from chick embryos, and have found by IIF that white blood cells are already positive for both antigens in 10-day-old embryos, the earliest date at which we could obtain adequate samples. An additional technique has been used to detect these viral antigens in Spafas lymphocytes. This consisted of competitive radioimmune assays using 'purified' labelled antigens and competition with 'cold' antigens from cells. For p27, lymphocytes showed weak activity and muscle, heart, liver, kidney and lung were negative. For gp85, lymphocytes showed greater activity than transformed mammalian cells used as positive controls, other tissues being negative.

The difference in expression of retroviral antigens between Spafas fibroblasts and lymphocytes, although both cell types contain the endogenous viral genome, indicates that some control over this expression must be exerted at the transcriptional or post-transcriptional level. Our results suggest that this regulation acts differently in different tissues of the same bird, as fibroblasts from a given individual can be totally negative whereas the leukocytes from the same bird express considerable quantities of both p27 and gp85. A similar observation has been reported for BALB/Mo mice infected at an early embryonic stage with Moloney leukaemia virus. After birth, viral antigen was found to be strongly expressed by splenic and thymic cells, but not by those of other tissues tested (liver, kidney and brain), although the viral genome was present in the DNA of all these organs<sup>10</sup>. This system is, however, not a natural

Fig. 1 Complement-dependent microcytotoxicity assay of anti-gp85 (AMV) serum against Spafas peripheral blood leukocytes. ■, Unabsorbed serum ( $n = 12$ ); □, serum absorbed on feather follicle fibroblasts from the same chicken (duplicate measures); △, serum absorbed on Spafas leukocytes ( $n = 4$ ). Bars represent s.d. In the absence of complement or with control negative sera the percentage of leukocytes killed is always  $\leq 20\%$ .

For IIF testing, blood samples were taken from four adult (4-month-old) Spafas chickens at 2-3-day intervals over a 15-day period. The blood was taken from the wing vein and collected into citrate. The leukocytes were separated either by allowing the cells to settle at 37°C and recovery of the buffy coat, or by centrifugation through Ficoll-paque (Pharmacia) at 1,500 r.p.m. for 15 min. Identical results were obtained using either method. After washing with phosphate-buffered saline (PBS), pH 7.4, the cells were smeared on to microscope slides, air dried, fixed in buffered formaldehyde (3.7% w/v) for 3 min, rinsed and postfixed in dry acetone for 10 min. Dilutions of antisera to p27 or gp85 raised in rabbits to purified polypeptides from avian myeloblastosis virus or control sera were then allowed to react with the fixed smears for 45 min at 37°C. After washing with PBS, the reaction was visualized by a further incubation with fluorescein-labelled goat anti-rabbit immunoglobulin serum (Behring, dilution 1:50) for 30 min at room temperature. The washed specimens were then examined under a Zeiss Ultraphot II fluorescence microscope. In some cases the surface expression of the antigens was estimated by the use of unfixed cell suspensions in a similar protocol. Control samples of cultured cell lines with known expression of the viral antigens were always included in each series. For cytotoxicity testing, the separated leukocytes were resuspended at  $6 \times 10^6$  cells  $ml^{-1}$  in RPMI 1640 medium supplemented with 10% inactivated fetal calf serum. This suspension (1  $\mu$ l) was introduced under liquid paraffin into each well of a 60-well Falcon microtitre plate together with 1  $\mu$ l of diluted antiserum. After 30 min at room temperature, 5  $\mu$ l of rabbit complement (Gibco), previously absorbed on adult chicken erythrocytes and brought to a dilution of 1:3, was added to each well and the incubation continued for 45 min. After this the dead cells were stained by the introduction of 5  $\mu$ l of a solution of eosin to each well, then, 2 min later, the cells were fixed by the introduction of 2  $\mu$ l of buffered formaldehyde (30% w/v, pH 7.0). The reactions were read under the phase-contrast microscope.

transmission of a strictly endogenous virus. In the same system there was no stimulation of viral expression in actively proliferating hepatocytes<sup>11</sup>, arguing against the hypothesis that endogenous virus expression might be simply associated with cellular proliferation.

The association of the expression of endogenous viral antigens with cells intimately involved in the animal's immune responses suggests some relationship between these molecules and the cell-surface (glyco)proteins implicated in immune reactions. The fact that viral antigens are expressed on most leukocytes suggests that these molecules may be involved in a general function of these cells rather than affecting only those cells and their clones specifically sensitized by antigen. Recently, Astrin *et al.*<sup>12</sup> have successfully reared to breeding age a healthy cockerel that has no endogenous viral DNA in its genome. It would be of interest to test the immune response of such birds and to compare it with that of birds carrying the endogenous virus.

Possibly the observed effect can be explained on the basis of artefact due to the culturing procedure itself. Fibroblasts might be negative for virus expression because of trypsinization or culturing. This explanation is, however, improbable as  $gs^- chf^-$  fibroblasts in these same conditions retain viral expression suggesting that  $gs^- chf^-$  fibroblasts are inherently negative. A more likely reason for the differential viral antigen expression may involve one of several control levels. For example, viral

RNA may be constitutively expressed in lymphocytes whereas it may require induction in fibroblasts.

Our results suggest that p27 expression takes place on the surface of lymphocytes. Although the 'usual' mode of expression of p27 is intracellular, a large precursor polypeptide containing the sequence of p27 has been shown to be present on the surface of cells infected by RSV, although in this case p27 antigenicity could not be demonstrated<sup>13</sup>. Alternatively, the lymphocyte plasma membrane might permit the insertion of p27 although that of fibroblasts does not.

These studies were supported by DGRST grant 78 7 2647 and by an INSERM fellowship to E.H. Some of the p27 and gp85 antisera, and the avian myeloblastosis virus antigens were gifts from Dr H. Diggelman and D. P. Bolognesi respectively.

## Genes which control cell proliferation in the yeast *Saccharomyces cerevisiae*

Peter E. Sudbery & Andrew R. Goodey\*

Bruce L. A. Carter

Department of Genetics, Lincoln Place Gate, Trinity College, Dublin 2, UK

In many eukaryotes it is thought that cell proliferation is regulated at a point in  $G_1$  close to the initiation of DNA synthesis<sup>1</sup>. Hartwell<sup>2,3</sup> and his colleagues have shown such a point in  $G_1$  phase in the budding yeast, *Saccharomyces cerevisiae*, defined by the *cdc 28* mutation. He has termed this point 'start' and showed that for cells to proceed beyond start, initiate DNA synthesis and produce a bud, various conditions must be met. Two of these conditions are the presence of adequate nutrients in the medium and the attainment of a critical size. We identify here some of the genes controlling start by isolating mutants which are altered with respect to the conditions in which start occurs. Two types of mutant have been isolated. One results in bud initiation when the parent cell is only half the size at which bud initiation occurs in wild-type cells. Such mutants define a single gene, *whi-1*, and they are apparently analogous to the size mutants isolated by Nurse and his colleagues<sup>4-6</sup> in *Schizosaccharomyces pombe*. A second type of mutation affects a second gene, *whi-2*, which is involved in the mechanism whereby cells arrest in  $G_1$  in stationary phase. *whi-2* cells growing exponentially initiate buds at the same size as wild-type cells. In stationary phase, however, *whi-2* cells, unlike wild-type cells, are predominantly budded and are smaller than wild-type cells.

\* Present address: The Brewing Research Foundation, Lyttel Hall, Nutfield, Redhill, Surrey RH1 4HY, UK.

Small cell-size mutants of strain X2180-1A were isolated by a procedure involving cell size separation by zonal centrifugation together with the use of the mating hormone  $\alpha$  factor. This procedure is described in detail elsewhere<sup>7</sup>. Three mutants, designated *whi A1*, *whi C7* and *whi D3*, which were recovered from different mutagenized cultures and are therefore independent mutations, were examined in detail. Parent cell volume of these mutants is shown in Table 1, together with dry mass measurements obtained by scanning interferometry and cell protein content for the wild type and the mutant *whi-A1*. Mutant cell size, whether measured by volume, protein content or dry mass, is approximately one-half that of the wild type. Volume was routinely measured as a parameter of cell size in further determinations.

**Table 1** Cell sizes of wild type and *whi-1*<sup>-</sup> mutants in exponential growth phase

| Strain        | Mother cell volume* ( $\mu\text{m}^3$ ) | Total cell protein† ( $\text{g} \times 10^{13}$ ) | Dry mass‡ at bud initiation (arbitrary units) |
|---------------|---|---|---|
| X2180-1A      | 47 ± 2                                  | 7.5   | 11.45 ± 0.38                                  |
| <i>whi-A1</i> | 25 ± 1                                  | 4.7   | 5.39 ± 0.48                                   |
| <i>whi C7</i> | 26 ± 2                                  | —   | —   |
| <i>whi D3</i> | 20 ± 1                                  | —   | —   |

\* Cells were inoculated from a YEPD plate into 2.5 ml YEPD medium in a 50 ml Erlenmeyer flask. The culture was shaken overnight at 25°C. The next day 0.1 ml of the late log phase culture was re-inoculated into 2.5 ml fresh medium and cultured in the same conditions for a further 5 h. Photomicrographs were prepared with a phase-contrast microscope at +400 magnification. Cells were concentrated by centrifugation if necessary. The negatives were projected and the major (a) and minor (b) axis of budded mother cells measured. The final magnification was measured using a photomicrograph of a stage graticule. Volume was calculated assuming a prolate spheroid shape according to the formula  $4/3\pi ab^2$ . Sufficient cells were measured so that the s.e.m. shown, was below 5% of the mean. This involved a minimum of 25 cells.

† Cells were cultured as above. Cell number per ml was measured with a Coulter counter following 10-s sonication to separate clumped cells. To measure protein per ml the cells were washed twice in distilled water and dissolved in 1 M NaOH at 100°C. Protein was estimated using the Folin test<sup>14</sup>.

‡ Unbudded stationary phase cells were diluted into fresh YEPD medium. At intervals samples were removed and mounted in a thin layer of gelatin on a slide<sup>15</sup>. Using a scanning interferometer<sup>16</sup>, the dry mass of cells which had just produced buds was measured. Measurements were continued until over 95% of the cells were budded. The errors are s.e.m.

Each mutant was crossed with XJB17-1 (*arg 9*, *his 4*, *ura 1*, *ilv 3*) and AN 33 (*arg thr*) both of which are  $\alpha$  mating type and produce buds at the same parent cell volume as X2180-1A. The parent cell volume for wild-type diploid cells is 81  $\mu\text{m}^3$  (Table 2). (A similar pattern of results is obtained if only zero bud scar class cells are considered.) The heterozygous diploids had cell volumes intermediate between those of wild-type haploid cells and diploid cells (Table 2). Thus the three mutant alleles are semi-dominant to the wild-type allele.

The heterozygous diploids were sporulated and tetrads dissected. The small phenotype segregated 2:2 in all tetrads showing that in each mutant it was due to a single nuclear mutation. Small progeny with appropriate combinations of mating type and auxotrophic markers were crossed together and diploids selected by prototrophic selection. These diploids all had a parent cell volume similar to that of wild-type haploids (Table 2).

Heteroallelic mutant diploids were sporulated and cell volume at bud initiation measured in the individual spore clones of the resulting tetrads. At least 20 tetrads were analysed in each of the three combinations but no wild-type recombinant pro-

geny were observed. Thus, the mutations probably affect the same gene, *whi-1*, although two closely linked genes could be involved.

If more than one gene is involved sequentially in the synthesis of a product controlling cell size, then the data shown in the last three lines of Table 2 may be used for complementation tests. Although the alleles are apparently showing dosage effects, if two alleles are in the same cistron then the heteroallelic diploid should be the same size as the homozygous diploid. If the alleles are in different cistrons then the heteroallelic diploid should be intermediate in size between the homozygous and heterozygous diploid. The data show the heteroallelic to be the same size as the homozygous diploid, showing the alleles to be in the same cistron. However, the predicted difference is small and may not be resolvable in the tests.

An alternative interpretation of the data, precluding the use of complementation tests, arises from the observation that the homozygous diploid is still twice the size of the mutant haploid even though neither will be producing any normal product from the *whi-1* gene. There is clearly an element of size control remaining which could be explained if there was a second gene so far undefined by mutation. The product of a second gene would act in parallel to that of the *whi-1* gene so that each would affect cell size directly. The size of the cell at bud initiation would therefore be proportional to the combined number of these two genes. The wild-type haploid would thus contain two genes and the wild-type diploid, four. The *whi-1*<sup>-</sup> haploid retains one gene, the homozygous diploid two and the heterozygous diploid three. The observed sizes of 20–25  $\mu\text{m}^3$  (*whi-1*<sup>-</sup> haploid), 45–50  $\mu\text{m}^3$  (wild-type haploid and homozygous mutant diploid), 60–65  $\mu\text{m}^3$  (heterozygous diploid) and 81  $\mu\text{m}^3$  (wild-type diploid) agree well with this interpretation. The results also predict that a second class of mutant, if isolated, could only be distinguished from *whi-1* mutants by recombination. Complementation could not be used, because the heteroallelic diploid would contain two functional genes whether or not the alleles were in the same or different genes.

The mutation *whi-2* apparently occurred spontaneously in strain M11. Whereas *whi-1* cells are smaller than wild type in both exponential growth and stationary phases, *whi-2*<sup>-</sup> mutants are approximately one-half the size of wild-type cells only in stationary phase (Table 3). In stationary phase these cells also differ from wild-type cells as: (1) the budding index is 24% compared with 1.6% of wild-type cells (Table 3). (2) The final cell density is approximately twice that of wild-type cells. (3) The cells have the phase-dark appearance characteristic of exponentially growing cells rather than the normal phase-bright appearance of stationary-phase cells (Fig. 1).

This phenotype suggests a lesion causing defective G<sub>1</sub> arrest. The cells undergo at least one more cycle of division in the absence of growth and consequently become smaller than wild-type cells.

*whi-2*<sup>-</sup> cells were crossed with 4/4D, a wild-type strain. In stationary phase the resulting diploid was phase-bright,

| XJB.9d.4a                     | <i>whi 1<sup>-</sup> whi 2<sup>-</sup></i>                                       | $8 \pm 1$                       | 3.60  | 31        | 10             |
| XJB.9d.4a $\times$ M11.13d.5d | <i>whi 1<sup>-</sup> whi 2<sup>-</sup> / whi 1<sup>-</sup> whi 2<sup>-</sup></i> | $19 \pm 1$                      | 1.95  | 47        | 5              |

Cells were inoculated from a YEPD plate into 2.5 ml YEPD medium in a 50-ml Erlenmeyer flask. They were cultured for 48 h at 25 °C, by which time cell number had stopped increasing and the culture considered to be in stationary phase. Cell volume of all cells was measured as described in Table 1 legend. After 10 s sonication, cell number was determined using a Coulter counter, percentage budding by microscopic examination, and per cent viable cells by plating out on YEPD plates at a suitable dilution and counting colonies that had appeared after 3 days.

unbudded and the mean cell volume was  $62 \pm 4 \mu\text{m}^3$ , only slightly less than the wild-type diploid in stationary phase ( $68 \mu\text{m}^3$ , Table 3). The mutation is therefore recessive. The diploid was sporulated and tetrads dissected; the phenotype segregated 2:2 in all 30 tetrads examined and therefore results from a single nuclear mutation.

M11 is a strain derived from DR19/T7 which<sup>7</sup> lacks the 2- $\mu\text{m}$  plasmid<sup>8</sup>. This trait is not associated with its absence. First, the trait segregates as a nuclear gene whereas the 2- $\mu\text{m}$  plasmid is inherited cytoplasmically. Second, *whi-2<sup>-</sup>* segregants from the above cross were shown to have received the 2- $\mu\text{m}$  plasmid when they were screened for its presence by buoyant density centrifugation.

A strain carrying the *whi-2* mutation was crossed with one carrying the *whi-1* mutation, the resulting diploid was sporulated and spore clones were grown to stationary phase and analysed for parent cell size. Wild-type recombinants were observed in some tetrads, which also contained spore clones

smaller in stationary phase than either *whi-1<sup>-</sup>* or *whi-2<sup>-</sup>* cells (Table 3). These are the reciprocal recombinant *whi-1<sup>-</sup> whi-2<sup>-</sup>*. The numbers of complete tetrad types was 1 Pd: 3 NPds: 13 Ts indicating unlinked genes. That the putative *whi-1<sup>-</sup> whi-2<sup>-</sup>* was a double mutant was confirmed in a further cross with wild type where the expected single mutant recombinants were recovered.

The stationary-phase appearance of wild-type, *whi-1<sup>-</sup>*, *whi-2<sup>-</sup>* and *whi-1<sup>-</sup> whi-2<sup>-</sup>* cells is shown in Fig. 1. *whi-1<sup>-</sup> whi-2<sup>-</sup>* mutants are much smaller than wild-type cells (Table 3). The high budding index (31%, Table 3), high final cell density (Table 3) and phase-dark appearance suggest continuing division. Cell size is only  $8 \mu\text{m}^3$  (Table 3) compared with the  $38\text{--}50 \mu\text{m}^3$  cell volume of wild-type cells in stationary phase and  $50 \mu\text{m}^3$  at which wild-type cells produce buds. Clearly, *whi-1<sup>-</sup> whi-2<sup>-</sup>* cells have lost much of their control over cell division.

The sizes of strains containing the *whi-2<sup>-</sup>* allele growing in exponential phase are shown in Table 4. The sizes are the same as the corresponding *whi-2<sup>+</sup>* strain indicating an abnormal

**Fig. 1** Phase-contrast pictures of stationary-phase haploid cells. *a*, Wild-type cells; *b*, *whi-1<sup>-</sup>*; *c*, *whi-2<sup>-</sup>*; *d*, *whi-1<sup>-</sup> whi-2<sup>-</sup>*. Stationary-phase cultures were prepared as described in Table 3 legend and photographed with a phase-contrast microscope. Final magnification  $\times 420$ .

phenotype is only expressed in stationary phase. This suggests that *whi-2* is not the gene whose existence was inferred from the size of *whi-1* strains. However, to investigate this further, the diploid *whi-1<sup>-</sup> whi-2<sup>-</sup>/whi-1<sup>-</sup> whi-2<sup>-</sup>* was isolated by mating double mutant haploids carrying complementary auxotrophic requirements. In stationary phase this diploid was extremely small ( $19 \mu\text{m}^3$ ), only 52% of the size of the wild-type haploid in similar condition. The doubly homozygous mutant diploid had the additional characteristic of the double mutant haploid—a high budding index. Furthermore, the size increased to that of a *whi-1<sup>-</sup>/whi-1<sup>-</sup>* strain when inoculated into fresh medium. In stationary phase the *whi-1<sup>-</sup> whi-2<sup>-</sup>/whi-1<sup>-</sup> whi-2<sup>-</sup>* homozygous diploid is larger than the *whi-1<sup>-</sup> whi-2<sup>-</sup>* haploid. Therefore, either an element remains which ensures an increase in cell size in the diploid, or no active size regulation remains and size increase is a result of a physical requirement for the accommodation of cellular organelles.

**Table 4** Cell volumes of *whi-2<sup>-</sup>* strains growing in exponential phase

| Strain     | Constitution                               | Cell size  |
|------------|--|------------|
| M11        | <i>whi-2<sup>-</sup></i>                   | $45 \pm 2$ |
| M11/44D    | <i>whi-2<sup>-</sup>/whi-2<sup>+</sup></i> | $90 \pm 4$ |
| XJB.9d.4a  | <i>whi-1<sup>-</sup> whi-2<sup>-</sup></i> | $18 \pm 1$ |
| XJB.9d.4a/ | <i>whi-1<sup>-</sup> whi-2<sup>-</sup></i> | $40 \pm 2$ |
| XJB.9d.10a | <i>whi-1<sup>-</sup> whi-2<sup>-</sup></i> |            |

Cells were grown in exponential phase as described in Fig. 1 legend.

The loss of size control and/or  $G_1$  arrest would reduce cell viability. Thus, wild-type cells are more viable than either *whi-1<sup>-</sup>* or *whi-2<sup>-</sup>* cells, which in turn are more viable than the *whi-1<sup>-</sup> whi-2<sup>-</sup>* double mutants (Table 3). However, many cells remain viable, possibly due to the action of the, as yet, undefined gene which may act in a similar manner to *whi-1*.

These studies show that cell size and  $G_1$  arrest are under separate genetic control. One gene, *whi-1*, controls cell size and its action is dose-dependent, as might be expected if cell size is normally proportional to ploidy<sup>9-13</sup>. This gene may correspond to the *wee-1* gene described by Nurse<sup>6</sup> in *S. pombe* and the conclusion that this gene codes for an inhibitor of cell division is consistent with our findings. Fantes *et al.*<sup>9</sup> concluded that elements must exist on the DNA exerting their influence on cell size according to their number. It was not clear how many such elements exist to a genome. The present study indicates that cell size is controlled by one or a small number of genes.

The second gene, *whi-2*, ensures that the cell cycle arrests in  $G_1$  when nutritional conditions no longer support growth. A *whi-1<sup>-</sup> whi-2<sup>-</sup>* double mutant is defective in both functions and has lost much of the control over cell division exhibited by wild-type cells.

P.E.S. and A.R.G. were supported by a SRC grant, B.L.A.C. by a grant from the Irish MRC. We thank Mr E. Gilmartin, Mrs D. Parkinson and Miss A. Watson for technical assistance, and the Berkeley Yeast Stock Centre for many of the strains used.

Mitochondria contain the simplest DNA molecules that are present in eukaryotes. Mitochondrial DNA (mtDNA) is easily purified, and is an important model system for studying eukaryote gene structure and basic molecular processes. The protein sequences of mitochondrial gene products have been shown to be conserved from yeast<sup>1-3</sup> to man<sup>4</sup>, and there are definite similarities at the DNA sequence level. In contrast, the overall organization of the mitochondrial genome is drastically different in these organisms. To understand this, we need to extend work on mtDNA to a wider range of species. We have chosen to study the mtDNA of *Aspergillus nidulans* because a particularly comprehensive analysis of this system can be achieved using genetics as well as biochemistry, and like most eukaryotes it is an obligate aerobe, whereas *Saccharomyces cerevisiae* is not. We have investigated whether defined pieces of particular yeast mitochondrial genes show enough homology to *Aspergillus* mtDNA fragments to enable the corresponding *Aspergillus* genes to be located on the physical map. The results reported here show that this is the case for all five genes tested, and present the first data on the physical organization of the structural genes in the mitochondrial genome of *A. nidulans*.

The yeast DNAs that we have used to locate homologous *Aspergillus* sequences by hybridization are derived from the mtDNA of particular well defined *petite* ( $p^-$ ) deletion mutants of yeast. The deletion is usually large and sometimes leaves as little as 0.1% of the mitochondrial genome intact, so that single genes or fragments of genes may be the only sequences remaining. The molecules actually used as probes for homology were 5'-end-labelled single strands of defined restriction fragments prepared as described in Fig. 1 legend. The five *petite* strains and the restriction fragments used are shown in Fig. 2.

*A. nidulans* mtDNA was cut with the restriction endonucleases *Hind*III or *Hae*III, and the fragments separated in an agarose gel and transferred to diazobenzyloxymethyl (DBM) paper<sup>5,6</sup>. After hybridization and autoradiography, we were able to show that specific yeast gene probes hybridized preferentially to particular restriction fragments from *A. nidulans* mtDNA (Fig. 1). This indicates a high degree of homology at the DNA sequence level between mitochondrial genes of these species.

We used this homology with yeast sequences to locate five *Aspergillus* mitochondrial structural genes on the physical map; the genes coding for subunits I, II and III of the cytochrome *c* oxidase complex, which we name [*oxiA*], [*oxiB*] and [*oxiC*], respectively, the gene coding for apocytochrome *b*, which we name [*cobA*], and a gene coding for subunit VI of the ATPase complex, which probably corresponds to the gene [*oliA*], previously identified genetically as giving rise to oligomycin-resistant mutants<sup>7</sup>. The parts of the yeast genes to which the five probes correspond are shown in Fig. 2. A restriction map of *Aspergillus* mtDNA is given in Fig. 3.

\* To whom reprint requests should be addressed.

**Fig. 1** Autoradiographs of Southern transfers of restriction endonuclease digests of *A. nidulans* mtDNA after hybridization to yeast mtDNA fragments. Mitochondrial DNA of *A. nidulans* strain *bi* A-1 was prepared by a modification of the method of Cummings *et al.*<sup>19</sup>. After restriction endonuclease digestion in 6.6 mM Tris-HCl pH 7.4, 6.6 mM MgCl<sub>2</sub>, 50 mM NaCl and 1 mM dithiothreitol, 2 µg of DNA was loaded per track of an 0.8% agarose gel<sup>20</sup>. After electrophoresis the gel was stained in ethidium bromide and photographed, then transferred to DBM paper<sup>6</sup> by the method of Southern<sup>7</sup>. Yeast mitochondria were prepared as described by Faye *et al.*<sup>21</sup>, and mitochondrial DNA purified as in Sanders *et al.*<sup>22</sup>. Restriction enzyme digests (all enzymes from Bethesda Research Laboratories) of yeast mtDNA were 5' end-labelled with [ $\gamma$ -<sup>32</sup>P]ATP (NEN)<sup>23</sup> using polynucleotide kinase (Bethesda Research Laboratories). The labelled fragments were denatured in 90% formamide and run into a 6% polyacrylamide gel to separate the strands of each fragment. The area of gel containing the strand to be used as a hybridization probe was cut out after identification by autoradiography and the DNA eluted from the gel and ethanol precipitated<sup>23</sup>. Preparation of the DBM paper and hybridization of labelled yeast mtDNA fragment single strands to the Southern transfer were carried out following Wahl *et al.*<sup>6</sup>, using 10% dextran sulphate in the hybridization mixture to improve the efficiency of hybridization<sup>6</sup>. The fragments used as probes for the various tracks, identified by their gene of origin, are *a*<sub>1</sub>, *a*<sub>2</sub> and *e*, *oxi*1; *b* and *f*, *oxi*2; *c* and *g*, *cob*; *d* and *h*, *oli*2; *i* and *j*, *oxi*3. *a*<sub>1</sub> and *a*<sub>2</sub> were from different series of experiments using formamide from Fluka and Merck, respectively. Tracks *a*<sub>1</sub>-*d* and *i* are of Southern transfers of *Hind*III digests, tracks *e*-*h* and *j* of Southern transfers of *Hae*III digests. The positions where DNA bands were present in the ethidium bromide-stained agarose gels before the Southern transfers are marked and numbered.

The yeast genes for cytochrome *c* oxidase subunits I, II and III are *oxi*3, *oxi*1 and *oxi*2, respectively. The probes for both *oxi*3 and *oxi*1 can be seen in Fig. 1 to hybridize to the large *Aspergillus* *Hind*III fragment 1 and to the 3,500-base pair *Hae*III fragment 3. This places the promoter-proximal half of [*oxi*B] (= *oxi*1) and the promoter-distal half of [*oxi*A] (= *oxi*3) within this *Hae*III fragment. The *oxi*2 probe hybridizes with *Aspergillus* mtDNA *Hind*III fragment 3 and *Hae*III fragment 4, placing the [*oxi*C] gene in the 2,500-base pair region between the large and small mitochondrial ribosome RNAs, together with a cluster of tRNA genes<sup>8</sup>.

**Fig. 2** Restriction fragments used as hybridization probes. The *petite* mutant strains used are named according to the yeast gene that they contain; they were DS200A1 (*oxi*1)<sup>2</sup>, DS40 (*oxi*2)<sup>24</sup>, DS6/A407 (*oxi*3) (unpublished), DS400/A12 (*cob*)<sup>25</sup> and DS14 (*oli*2)<sup>3</sup>. The bar above the line indicates the position of coding regions of the gene in each case; the numbers indicate base pairs starting from the NH<sub>2</sub>-terminal coding end. Arrows show the direction in which NH<sub>2</sub> or COOH terminal-coding regions would lie if they were in the *petite*. The *Hin*II-TaqI *oxi*3 ([*oxi*A]) probe contains only exon 5, which is towards the promoter-distal end of the *oxi*3 split gene. The *oxi*1 ([*oxi*B]) probe corresponds essentially to the promoter-proximal coding half of the gene, the *oxi*2 ([*oxi*C]) probe to the promoter-distal half of the gene. The *cob* gene probe is part of the first exon of this split gene and the *oli*2 ([*oli*A]) probe corresponds to the promoter-distal two-thirds of this gene. All *petites* have been completely sequenced<sup>2,3,24,25</sup>. The solid bar below the line gives the position and length in base pairs of the restriction fragment used as a probe. Other symbols show the position of restriction endonuclease recognition sites. ▲, *Hin*II; ★, *Hind*III; ↑, *Taq*I; ●, *Mbo*I; ■, *Eco*RI; bp, base pairs.

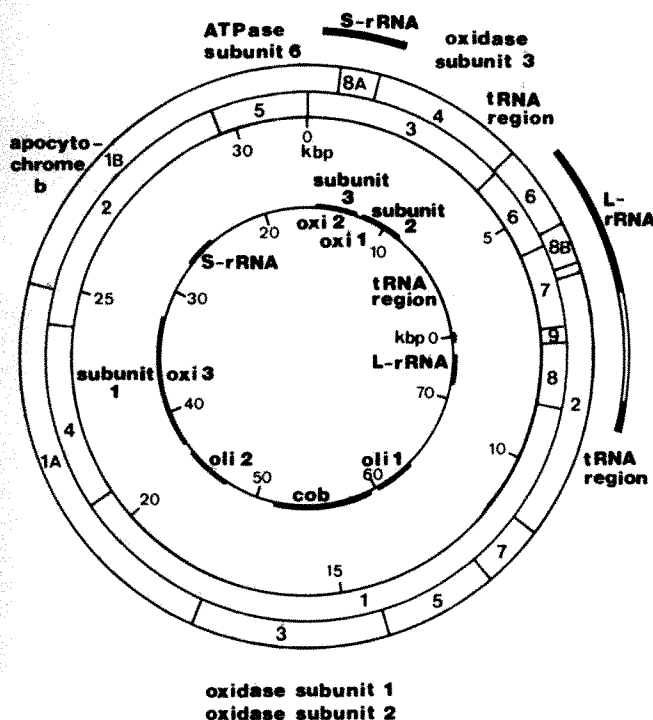

*Aspergillus* mtDNA. The *oli1* gene maps to the *Hae*III fragment 1A or 1B. The *oli2* gene maps to the *Hind*III fragment 5 at the [*cobA*] gene lies in this region (Fig. 1). Mutations in mitochondrial genes can give rise to a growth defect phenotype. Both genes code for subunits of the cytochrome *c* oxidase complex; the *oli1* gene codes for the cytochrome *c* oxidase subunit I, the *oli2* gene for subunit VI of the cytochrome *c* oxidase complex. Previous genetic work on oligomycin resistance in *Aspergillus* has shown that one gene maps in the mitochondrial genome ([*oliA*]<sup>10</sup>; the [*oliB*] group of mutations maps to a small part of [*oliA*]) and one in the nuclear genome [*oliC*]. Figure 1 shows that a yeast *oli2* gene probe hybridizes to *Hind*III fragment 5 of *Aspergillus* mtDNA and to *Hae*III fragment 1A or 1B (presumably to 1B). An *Aspergillus* mitochondrial gene thus corresponds to the *oli2* gene of yeast, maps between the [*cobA*] gene and the small rRNA and probably corresponds to the [*oliA*] gene.

which is a mitochondrially inherited suppressor of [*cs-67*]. Genetic mapping<sup>11</sup> has shown [*camA*], [*cs-67*] and [*sumD*] to be linked in the order given; [*oliA*] is unlinked to these genetically. We can locate [*oliA*] precisely on the physical map. All the other mutations probably affect the mitochondrial ribosome and thus represent mutations either in mitochondrial rRNA or in a gene coding for a ribosomal protein, analogous to the yeast *var-1* gene<sup>16</sup>.

The overall plan of the mitochondrial genome of *Aspergillus nidulans* has some similarity to that of *S. cerevisiae*, although they differ considerably in size (*A. nidulans* 31.5 kilobase pairs, *S. cerevisiae* 75 kilobase pairs) and gene arrangement. In both organisms the mitochondrial rRNA genes are not contiguous, and the large rRNA gene is split by an intron<sup>17</sup>. The space between them is very large (25 kilobase pairs) in *S. cerevisiae*, and contains the *oxi1* and *oxi2* genes and a cluster of tRNA genes<sup>1</sup>, whereas in *A. nidulans* they are separated by only 2.5 kilobase pairs containing the [*oxiC*] (= *oxi2*) gene and part of the tRNA gene cluster. The two rRNA genes, [*oxiC*] (= *oxi2*), [*cobA*] (= *cob*) and [*oliA*] (= *oli2*) have the same positions relative to one another in the two organisms, although the distances between them are quite different. The *Aspergillus* equivalent of the yeast mitochondrial *oli1* gene is in the nucleus<sup>18</sup>. The [*oxiA*] (= *oxi3*) and [*oxiB*] (= *oxi1*) genes are in the mitochondrial genome in both organisms, but in very different positions. The coding sequences of all five genes must be remarkably strongly conserved to show such clear hybridization specificity. In coding regions that have been sequenced, up to 60% of the amino acids and 72% of the base pairs are the same in *S. cerevisiae* and *A. nidulans* (R.W.D. *et al.*, unpublished).

All the differences between the mitochondrial genome of *A. nidulans* and *S. cerevisiae* reported here can be explained by a series of inversion or translocation events. The comparatively small size of *Aspergillus* mtDNA is due to the loss of large tracts of A + T-rich noncoding sequences, and of (at least) one gene to the nucleus. We do not know if any of these changes have any relationship to the switch from facultative to obligate aerobiosis. The technique used here provides a quick and convenient method for mapping mitochondrial genes at least in other lower eukaryotes and potentially allows us to follow gross changes in mitochondrial genome structure throughout the evolutionary process.

This work was supported by MRC project grant G979/429/C to R.W.D. and C.S.

**Fig. 3** Location of mitochondrial structural genes of *A. nidulans* on the physical map. Circular physical maps of *S. cerevisiae*<sup>1</sup> and *A. nidulans* mtDNA<sup>17</sup> are given, arranged so that the large and small rRNA (L- and S-rRNA) genes of the two organisms are in similar positions. Distances are given in kilobase pairs (kbp). In the *A. nidulans* map the inner circle shows the *Hind*III fragments, the outer circle the *Hae*III fragments<sup>17</sup>. The restriction map was confirmed by us for the strains used in this work. The positions of the rRNA genes and the tRNA cluster are based on refs 17 and 18, respectively. In terms of *Aspergillus* gene symbols, apocytochrome *b* = [*cobA*], ATPase subunit 6 = [*oliA*], oxidase subunit 1 = [*oxiA*], 2 = [*oxiB*], 3 = [*oxiC*].

The hybridization results are summarized in Fig. 3. Previous information about the nature and relative positions of *Aspergillus* mitochondrial genes has come from recombinational mapping<sup>11,12</sup> of mitochondrially inherited mutations<sup>13</sup>. Five classes of such mutations are known in *Aspergillus*: [*oliA*]<sup>10</sup>, conferring oligomycin resistance, [*camA*] and [*camB*] (probably in the same gene), conferring chloramphenicol resistance<sup>7,14</sup> [*cs-67*], which is a cold-sensitive mutation<sup>15</sup> and [*sumD*]<sup>13</sup>,

## Comparison of benzo(a)pyrene metabolism and sister chromatid exchange induction in mice

Rhona R. Schreck & Samuel A. Latt

Division of Genetics and Mental Retardation Center, Children's Hospital Medical Center and Department of Pediatrics, Harvard Medical School, Boston, Massachusetts 02115

**Genetic differences in the inducible arylhydrocarbon hydroxylase (EC 1.14.14.2) (AHH) system, which is involved in the multi-step metabolism of hydrocarbons, are known to exist in both humans and mice<sup>1-4</sup>. However, the predictive value of AHH activity in human or murine tissues, assayed as benzo(a)pyrene hydroxylation, as an index of individual susceptibility to mutagens and carcinogens, remains unclear<sup>5-8</sup> because of apparent inconsistencies between results obtained from different *in vitro* and *in vivo* systems. This situation may in part reflect the complexity of the pathways involved in drug metabolism, which combine both activation and detoxification. To determine the relationship of metabolic potential to an easily quantified, short-term *in vivo* end point of genetic damage, we compared the ability of AHH inducible and uninducible mice to metabolize a procarcinogen, benzo(a)pyrene (BP), with the *in vivo* induction by BP of sister chromatid exchanges (SCEs). SCE induction has been shown to correlate with mutagenesis<sup>9,10</sup>. We report here that although BP did cause an increase in SCEs in test animals, the extent of this increase did not differ between the inducible C57BL/6 mice and the uninducible DBA/2 mice. Moreover, prior exposure to an AHH inducer, 3-methylcholanthrene (3-MC), did not increase the number of BP-induced SCEs in C57BL/6 mice. This lack of correlation between benzo(a)pyrene hydroxylase (BP-OH) inducibility and SCE response reinforces the idea that other metabolic steps, such as detoxification or DNA repair, may influence the overall genetic impact of a drug.**

Mice were examined for their ability to convert BP to the fluorescent product 3-hydroxybenzo(a)pyrene, as a measure of the early metabolism of this drug by the AHH system<sup>11</sup> (Fig. 1). C57BL/6 was used as the inducible strain as these mice show BP-OH induction in both the liver (Fig. 1a, b) and bone marrow (Fig. 1c) in response to prior administration of 3-MC. DBA/2 was used as the uninducible strain as these mice showed no hepatic enzyme induction (Fig. 1d, e) in response to 3-MC and only minimal enzyme induction in peripheral tissues (Fig. 1f).

The same mouse strains were also tested for epoxide hydrolase (EC 4.2.1.63) activity, the second enzyme in the proposed metabolic pathway of BP to its ultimate carcinogenic form<sup>12</sup> (Table 1). There was no significant difference in epoxide hydrolase activity between the two strains, and neither strain showed 3-MC inducibility for this enzyme.

Having confirmed differences in AHH activity between the two strains, these mice were used for *in vivo* SCE analysis following partial hepatectomy as previously described<sup>13</sup> with or without prior 3-MC induction. BP-induced SCEs were scored in both liver and bone marrow cells and the results from multiple animals pooled (Fig. 2). The data were compared by a two-tailed *t*-test which took into account differences in baseline SCE frequencies.

Although prior 3-MC treatment produced a 6.8-fold increase in BP-OH activity in regenerating liver of the inducible C57BL/6 mice (Fig. 1b), this pretreatment did not alter the number of BP-induced SCEs in either the liver or bone marrow of this strain (Fig. 2a, b). A small increase in baseline SCE frequencies was observed with induction, attributable to the 3-MC itself, which is metabolized by the AHH system and known to induce SCEs when activated<sup>14</sup>. However, there was no statistically significant difference in BP-induced SCEs above this

baseline effect with and without prior BP-OH induction by 3-MC.

Both the inducible and uninducible strains, in the absence of enzyme induction, showed fairly similar SCE induction in liver cells in response to BP (Fig. 2a, c;  $P > 0.1$  at 50 and 200 mg per kg BP), although the DBA mice showed a slightly larger SCE response to BP in bone marrow (Fig. 2b, d;  $P < 0.01$ ) than did C57BL/6 mice. Our previous observation that reduced liver function can lead to an enhanced response to clastogens in peripheral tissues<sup>13</sup> may account for this effect, as well as the observation of Nebert<sup>15</sup> that nonresponsive mouse strains exhibit larger drug-induced effects in distant tissues than do responsive mice.

In contrast to the results in BP, the induction of SCEs in response to 3-MC differed markedly between the two mouse strains. In C57BL/6 mice, 3-MC caused only a small increase in SCE frequencies (from 6.2 to 8.7 SCEs per cell, Fig. 2a, b), but effected a marked increase in enzyme activity (Fig. 1b, c). In contrast, in the DBA/2 mice, 3-MC does not induce AHH activity, but it produces a large increase in SCE frequencies (from 5.1 to 15.9 SCEs per cell, Fig. 2c, d), even 2 days after its administration. This result may be due to the prolonged persistence of 3-MC in the strain with the lower metabolic capabilities.

The inability of BP to induce additional SCEs over the heightened baseline level in 3-MC-treated DBA mice (Fig. 2c, d) remains unexplained. It does not reflect a saturation of the SCE response, because higher levels of SCEs per cell can be obtained with other drugs<sup>13,16</sup>. The lack of additional SCE induction might instead reflect some form of competition (between the two hydrocarbons, 3-MC and BP), perhaps for limited metabolic enzymes or the cytoplasmic receptor known to be deficient in DBA mice<sup>15</sup>.

The metabolism of BP can involve multiple pathways leading to a variety of products, many of which are capable of reacting with DNA. 3-MC treatment of inducible mouse strains has been reported to induce a distinct class of cytochromes that activate hydrocarbons such as BP to their ultimate carcinogenic form, in this case the 7,8-diol-9,10 epoxide<sup>17</sup>. In the present

**Fig. 1** Benzo(a)pyrene hydroxylase activity in intact liver (a, d), regenerating liver (b, e) and bone marrow (c, f) of C57BL/6 (a, b, c) and DBA/2 (d, e, f) mice. Activity expressed as percentage of control activity (open bars) seen with either phenobarbital (PB) (hatched bars) or 3-methylcholanthrene (3-MC) (solid bar) induction. Hepatectomy, when done, immediately preceded induction. Bone marrow was collected from non-hepatectomized mice. Animals received either three daily injections of 80 mg phenobarbital (Sigma) per kg in 8% ethanol or 80 mg 3-MC (Sigma) per kg in corn oil. Controls received no injection. Tissue was collected at 72 h after induction from PB-treated animals, at 50 h from 3-MC-treated animals and 67 h from control animals (times reported to be maximal for enzyme induction)<sup>28-30</sup>. Livers were homogenized and bone marrow cells sonicated in 0.15 M KCl and the 9,000g supernatant (S-9) material used in the enzyme assays. Liver S-9 was incubated for 5 min and bone marrow for 20 min in 56 mM Tris, 2.8 mM MgCl<sub>2</sub>,  $3.7 \times 10^{-4}$  M NADPH,  $4.3 \times 10^{-4}$  M NADH, 0.6 mg ml<sup>-1</sup> albumin with  $8.5 \times 10^{-5}$  M BP ( $\epsilon_{384.5} = 27,542$  in methanol). The reaction was stopped with hexane/acetone (3.75:1 v/v). After mixing, the organic phase was extracted with 1 M NaOH and the fluorescence read with a Perkin-Elmer MPF-3 (excitation 396 nm; emission 522 nm)<sup>11</sup>. This fluorescence was compared with that of pure 3-hydroxy-benzo(a)pyrene ( $\epsilon_{380} = 36,300$  in alcohol) and activity expressed as pmol 3-OH-BP formed per mg S-9 per min. Bone marrow activity was 1/1,000th of that in liver.

Table 1 Epoxide hydase activity in regenerating mouse liver

| Induction            | C57BL/6  | DBA/2     |
|----------------------|----------|-----------|
| None                 | 245 ± 72 | 243 ± 80  |
| Phenobarbital        | 523 ± 41 | 354 ± 138 |
| 3-Methylcholanthrene | 292 ± 81 | 262 ± 109 |

Activity is expressed as pmol <sup>3</sup>H-styrene glycol formed per min per mg S-9, measured by the conversion of <sup>3</sup>H-styrene oxide (Amersham, specific activity 88 mCi mmol<sup>-1</sup>) to styrene glycol<sup>27</sup>. Approximately 2.5 mg liver S-9 was incubated with 125 mM Tris (pH 9.0, with 0.025% Tween) and 1 mM styrene oxide (diluted with cold reagent to 190,000 c.p.m.) for 30 and 60 min. After two extractions with *n*-hexane, the reagent mixture was extracted with 2 ml ethyl acetate and 200-μl aliquots counted in a Beckman LS8000 scintillation counter. Each value represents the mean of four trials ± s.d.

experiments, the number of SCEs induced by BP *in vivo* was independent of the AHH inducibility of the mouse strain used or the exposure of inducible mice to 3-MC. The lack of correlation between AHH inducibility and SCE induction suggests either that constitutive AHH activities and products thus formed are responsible for the SCE induction observed or that the involvement of other enzymes in the metabolic pathway, such as epoxide hydase, obscures any differences which may exist in the AHH system.

This lack of correlation between metabolic potential expressed as AHH activity and biological end points has been observed previously. For example, no relationship was observed between AHH inducibility and the *in vitro* induction of SCEs by BP<sup>18</sup>, the activation of BP by S-9 fractions to a mutagen in the Ames test<sup>19,20</sup>, the induction by hydrocarbons of tumorigenesis in humans<sup>6</sup> or in mice<sup>8</sup>, or the extent of covalent binding of BP metabolites to DNA<sup>21</sup>. Several of these effects can, however, be enhanced by inhibiting epoxide hydase activity<sup>22,23</sup>, suggesting that this enzyme, which shows no variability between the two strains examined, may have a critical role. Developmental differences in epoxide hydase levels<sup>24</sup> or in other metabolic enzymes<sup>25</sup> may explain a recent study<sup>26</sup> of the effect of BP on isolated early mouse embryos, in which AHH activity was not measurable, and a larger SCE increment was observed in inducible strains than in noninducible strains.

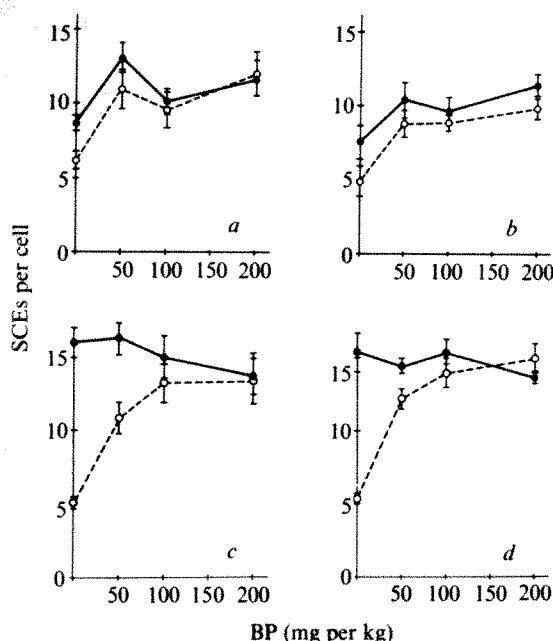

Fig. 2 Induction of SCEs by benzo(a)pyrene (BP) in the liver (a, c) and bone marrow (b, d) of partially hepatectomized (two-thirds removal of liver) C57BL/6 (a, b) and DBA/2 (c, d) young (7-9 weeks) female mice (Charles River) with (solid line) and without (broken line) prior 3-MC treatment (as in Fig. 1). Animals received BP by intraperitoneal injection (53 h post-hepatectomy) followed by a series of 10<sup>-2</sup> M bromodeoxyuridine injections. The following day the animals received two 0.4-ml injections of colchicine (0.2 mg ml<sup>-1</sup>) and liver and bone marrow cells were collected from each animal. Each point on the graph represents the mean of three to six animals (a minimum of 20 cells was examined per animal) and the error bars indicate s.e.

The inability to demonstrate clear and consistent relationships between AHH inducibility and a variety of genetic responses, including SCE induction, suggests that other biological pathways including alternative activation and detoxification, and perhaps DNA repair, influence the end points obtained. The complexity of steps involved in reaching a biological end point thus makes measurement of a single enzyme in the metabolic pathway unreliable as a predictor of an individual's susceptibility to the *in vivo* effects of a procarcinogen.

This work was supported by NIH grant HD 04867 and American Cancer Society grant CD-36E. We thank Dr I. J. Paika and Mr M. E. Eisenhard for their assistance, Dr J. Felton for providing details of the BP-OH assay and the NCI Chemical Repository (ITT Research Institute, Chicago) for providing the 3-hydroxybenzo(a)pyrene.

The nature of the precise packing of collagen molecules into a collagen fibril, producing the characteristic regular banding, is still debatable. The problem has been approached using electron microscopy and X-ray diffraction techniques, and several models have been proposed, including hexagonal packing, an octafibril structure, a two-strand rope and a five-strand rope (for review, see ref. 1). For the past decade the penta-fibrillar model, originally proposed by Smith<sup>2</sup>, has been widely accepted as the fundamental building unit. This model, based on the quarter-stagger end-overlap hypothesis of Hodge and Petruska<sup>3</sup>, was

**Fig. 1** Projection of the hexagonally packed collagen molecules along their axis. The small distortions of the lattice<sup>5</sup> and the slight ( $4^\circ$ ) tilting of the collagen molecules are not shown. The numbers 1–5 refer to the molecular segments (see lower left) in one 66.8-nm (D) thick transverse section. The packing arrangement may be considered as horizontal layers of the quarter-stagger end-overlap<sup>3</sup> system, running 1 to 5 from right to left, with successive layers displaced from left to right by 3.78 nm, thus generating the unit cell<sup>5</sup> outlined.

supported by the X-ray diffraction data of Miller and Wray<sup>4</sup>. These X-ray data have now been reinterpreted by Hulmes and Miller<sup>5</sup> in terms of a quasi-hexagonal packing of collagen molecules. We argue here that until other characteristic parameters are taken into account, in particular the chemical cross-linking evidence, the packing problem is still unresolved.

The recently proposed model<sup>5</sup> involves the juxtaposition of the collagen molecules in a slightly distorted two-dimensional hexagonal lattice, having a specific tilt of about  $4^\circ$  between the collagen molecules and the normal to the basal lattice plane, together with some longitudinal shear. The model is a development of the packing arrangement proposed by McFarlane<sup>6</sup>. The apparent advantage of this model is that it provides a better fit with the X-ray diffraction data compared with other models. Note that both models (the penta-fibrillar rope and the quasi-hexagonal arrangement) rely essentially on the same X-ray diffraction data.

These three-dimensional structures must incorporate the quarter-stagger end-overlap array<sup>3</sup> to generate the banding pattern observed by electron microscopy. However, none of these models considers the characteristic chemical cross-linking evidence of collagen. In particular, the new quasi-hexagonal model does not account for the restrictions on proposed molecular arrangements imposed by the known location of the intermolecular cross-links.

A cross-section through the proposed quasi-hexagonal model perpendicular to the collagen fibrillar axis is shown schematically in Fig. 1. The numbers 1–5 represent specific distances along the collagen molecules commensurate with the D-stagger in the end-overlap model<sup>3</sup>. To fit the basic features of the X-ray diffraction pattern<sup>4</sup>, Hulmes and Miller<sup>5</sup> stagger successive layers laterally (see Fig. 1) by 3.78 nm relative to each other, generating the 3.78-nm row lines observed in the X-ray fibre diffraction patterns<sup>4</sup> and developing a two-dimensional lattice defined by  $a = 2.607$  nm,  $b = 3.903$  nm with  $\gamma = 104.58^\circ$  (Fig. 1).

The location of the bifunctional cross-links has been established by biochemical techniques for the fibrous types of collagen, type I<sup>7,8</sup>, type II<sup>9,10</sup> and type III<sup>11,12</sup>, as only occurring between the telopeptide lysine-aldehyde and the  $\epsilon$ -NH<sub>2</sub> group of specific lysine or hydroxylysine residues 25 nm from either end of the molecule, that is, the end of the overlap region (Fig. 2a). We have now extended these observations to mature tissue and have demonstrated that cross-linking occurs through polymeric interactions involving the C-terminal non-helical

region of  $\alpha 1CB6$  and the helical peptide  $\alpha 1CB5$ . This polymeric cross-linked material, poly- $\alpha 1CB6$ , has been isolated from mature bovine tendon and partially characterized<sup>13,14</sup>. The important factor relating to the molecular structure of the fibres is that this cross-linking arrangement can only occur if the C-terminal ends of the molecule are in register. In terms of the numerical notation of the D-stagger of the molecules, the  $\alpha 1CB6$ - $\alpha 1CB5$  dipeptide is classified as 1, 5—the molecules align in the lattice such that 1's are adjacent to 5's and vice versa. In the fibre structure, individual collagen molecules must experience neighbours staggered by D and have at least one neighbour aligned in longitudinal register to generate limited interconnections of the type 1, 5; 1, 5; 1, 5 within the fibre, thereby generating poly- $\alpha 1CB6$  (Fig. 2b).

Analysis of the new structure proposed by Hulmes and Miller<sup>5</sup> shows that such a cross-link scheme is unattainable. Furthermore, if to accommodate this packing restriction the molecules in the structure are moved longitudinally or laterally, then the proposed unit cell on which the X-ray argument is based will have to change. This model must therefore be adapted to fit the cross-linking data. This can readily be achieved if C-terminals in successive layers are juxtaposed with reducible cross-links between  $\alpha 1CB6$  and  $\alpha 1CB5$  (or 1, 5 in quarter-stagger nomenclature) to form a polymer containing 1:1 proportions of  $\alpha 1CB6$  and  $\alpha 1CB5$ . Analysis of poly- $\alpha 1CB6$  did indeed show an approximate 1:1 ratio of these two peptides<sup>14</sup>. Hence, by using the cross-linking data to modify the model suggested by the physical data, a detailed and more accurate quasi-hexagonal model could be postulated.

**Fig. 2** a, Schematic quarter-staggered array of collagen molecules showing the location of a reducible cross-link between  $\alpha 1CB6$  and  $\alpha 1CB5$  peptides and the resultant 'H' peptide derived from a cyanogen bromide digest. b, Diagrammatic representation of the proposed formation of poly- $\alpha 1CB6$ . Layers of quarter-staggered collagen molecules are shown in register, that is, layer 1 is in register with layer 2 which is in register with layer 3. Each reducible cross-link between  $\alpha 1CB6$  and  $\alpha 1CB5$  is aligned and closely packed with a reactive residue in the adjacent  $\alpha 1CB6$  peptide in the molecule in the next layer, thus several layers can be interlinked by repeating this simple additive process.

Recent evidence on variations in fibre size from electron microscopy has suggested that there is a basic building fibril of about 8.0 nm<sup>15</sup>. Similarly, the X-ray evidence of Nemetschek<sup>16</sup> using stained fibres provides strong evidence for a unit cell of 8.0 nm, contrasting with the 4.0-nm cell of the other pentafibril and hexagonal models. These data have received recent support from the electron diffraction studies of Squire and Freundlich<sup>17</sup>. Fraser's group suggests<sup>18</sup> that four pentafibrils align in register to form such an 8.0-nm unit, which they term the tetragonal cell or unit. Considering the restrictions that such a structure puts on the possible extent of formation of polymeric cross-linked material, this model similarly, in its simplest form, cannot readily be adapted to fit the chemical evidence. Intrapentafibrillar reducible cross-links can be formed relatively easily so that the unit itself is stabilized. However, when these cross-links are stabilized by addition reactions with other aligned C-terminals in other pentafibrils, only internal interactions within the tetragonal unit seem possible due to the large interatomic distances between sites in different units. This would seem to limit the maximum molecular weight of the resultant polymeric cross-linked material to a much lower range than that actually observed. A further difficulty with this model concerns the discrepancy between observed and calculated densities, as discussed by Hulmes and Miller<sup>5</sup>.

It might be profitable to view the hexagonal models<sup>6,5</sup> as being built up from groups of five collagen molecules (or multiples as favoured by the larger unit cells suggested by the more recent X-ray evidence of Nemetschek<sup>16</sup>), each lying on a hexagonal lattice site (or a slightly distorted hexagonal lattice in the final analysis) so that they form a collapsed pentafibril which in turn aligns with other such units to complete a full two-dimensional array. Certainly, between the extremes of the McFarlane model<sup>6</sup> and the Hulmes and Miller model<sup>5</sup>, there might be scope for organizing limited runs of 1, 5 interconnections.

The parameters which govern the organization of such interactions may be determined by considering the precise restrictions imposed on the structure of the collagen fibril by the known characteristics of poly- $\alpha$ 1CB6 as follows. (1) The bifunctional cross-links formed between staggered molecules to give the 1, 5 interactions must limit the movement of the non-helical region involved. (2) Chemical evidence strongly suggests that the stable cross-link is produced by an addition reaction of a reactive group in an adjacent molecule with the bifunctional cross-link. An exogenous molecule (such as a lipid) could be involved as a chemical bridge in this reaction, in which case the intermolecular distances of the collagen molecules need not be restricted. However, no evidence exists for such a mechanism and, given the precise collagen molecule packing, this pathway is extremely unlikely. The most feasible mechanism would involve a reactive side chain in the nearest-neighbour collagen molecule. This prediction limits the possible intermolecular distance to a maximum of the length of the longest amino acid side chain. (3) The experimental data suggest that the range of poly- $\alpha$ 1CB6 polymers characterized would be formed from the interactions of molecules in 5–10 layers of close-packed collagen sheets.

Clearly, the rigorous application of the chemical evidence can profoundly affect the types of model constructed to explain the physical data. Model building is of considerable value but has severe limitations, particularly if all lines of evidence are not accounted for. Definitive chemical evidence on cross-linking is now available and should be regarded as at least as important as the physical data and may, indeed, ultimately prove to be the most crucial criterion for unravelling higher molecular organization in the collagen matrix.

After submission of this paper various arrangements of the collapsed pentafibril model similar to that proposed by us was postulated by Trus and Piez<sup>19</sup>, but without consideration of the chemical cross-linking evidence.

## Direct observation of a transverse periodicity in collagen fibrils

John M. Squire & Alan Freundlich

Biopolymer Group, Department of Metallurgy and Materials Science, Imperial College, London SW7 2BP, UK

Collagen fibrils have been extensively studied by electron microscopy, but only scant evidence has yet been obtained about their transverse structure. A transverse periodicity of about 40 or 80 Å might be expected if the microfibril model (until recently the common preference) is correct<sup>1–9</sup>, but little direct evidence for such a periodicity has been obtained so far. We have studied electron micrographs of longitudinal cryosections of rat tail tendon. These appear very fibrous when studied by eye, but they produce at best only weak diffuse equatorial peaks in optical diffraction patterns. Nevertheless, we show here that like other fibrous protein structures, they do possess a strong transverse periodicity as revealed by their self-convolution functions (or auto-correlation functions)<sup>10–12</sup>. The observed periodicity is consistent with the presence of an 80 Å structural unit in collagen fibrils *in vivo*.

Many aspects of the structure of collagen fibrils have been satisfactorily accounted for in recent years. The chain conformation in tropocollagen molecules has recently been refined by Fraser *et al.*<sup>13</sup>, and the axial striation patterns in positively stained aggregates of collagen have been correlated well with the known amino acid sequence of the  $\alpha$ 1 collagen chains<sup>14–21</sup>. The sequence studies show that the characteristic *D*-period of about 670 Å in collagen fibrils is due to the 670 Å axial stagger between molecules and that this stagger, or a multiple of it, is such that the number of polar and apolar interactions between adjacent molecules is maximized.

However, considerable controversy remains about the arrangement of collagen molecules in a transverse view of a collagen fibril. For several years the favoured model was one in which fibrils were formed from an ordered near-tetragonal array of microfibrils of diameter ~38 Å and probably containing five strands of tropocollagen molecules. Four such microfibrils, each twisted to have 4<sub>1</sub> helical symmetry, would then be related by an approximate 4<sub>3</sub> screw axis to give a repeating unit about 80 Å square<sup>1,3,6,9</sup>. Other published models also have microfibrils 38 Å in diameter but containing differing numbers of strands<sup>4,5,7,8</sup>. In support of such structures there have been several observations of individual filamentous elements about 40 Å in diameter in electron micrographs of collagen preparations (see refs 22 and 23). In addition, Parry *et al.*<sup>24,25</sup> have recently reported that in many types of connective tissue the fibril diameters are always multiples of about 80 Å; a result clearly favouring the existence of an 80 Å structural unit.

But a radically different model for collagen structure has recently been proposed by Hulmes and Miller<sup>26,27</sup>. This model explains the observed X-ray diffraction data on collagen<sup>2</sup> not in terms of a near-tetragonal lattice of microfibrils, but rather in

**Fig. 1** *a*, Electron micrograph of part of a negatively stained, fixed collagen fibril from rat tail tendon (fibril axis vertical) showing the characteristic pattern of alternating dark (stain filled) and light (stain excluding) bands which together define one *D*-period (*D*). In molecular terms the dark band (*G*) is the gap region in the modified quarter-stagger model of Hodge and Petruska<sup>38</sup>, and the light band (*O*) is the region of molecular overlap. Within the dark band between the arrowheads thin vertical strands of protein (white) can be seen. The self-convolution function of this single dark band is shown in *b*. As indicated by the arrows, regularly spaced vertical white lines can be seen in the convolution indicating that the strands in *a* have a well-defined average lateral separation. In *a*, *D* is 708 Å and in *b*, *s* (the lateral period between adjacent arrowed lines) is 55 to 60 Å. Note that the convolution *b* is enlarged relative to *a*.

terms of a molecular crystal<sup>28</sup> in which straight collagen molecules, somewhat tilted to the fibril axis, pack in a quasi-hexagonal lattice<sup>29</sup>. Miller<sup>27</sup> has shown that such a model can account well for the intensity distribution in the equatorial and near-equatorial regions of the observed X-ray diffraction pattern and it explains some features not accounted for by the tetragonal lattice.

It is by no means clear, however, that this new model could explain the 80 Å increments in fibril diameter observed by Parry *et al.*<sup>24-25</sup>. On the other hand, one might expect from these observed diameters that it should be possible to see an 80 Å lateral periodicity in electron micrographs of collagen fibrils. But only in one reported case<sup>30</sup> have sections of collagen fibrils revealed the presence of an 80 Å periodicity. The fibrils, which were very different in character from those in tendon, were from the inner layers of the dogfish egg capsule and they showed a square lattice of side 80 Å in transverse sections. No such structure has yet been reported in connective tissue from higher vertebrates.

In an attempt to study the transverse structure in rat tail tendon, we are using the relatively novel cryosectioning technique, which we have successfully applied to muscle<sup>31,32</sup>, to obtain both transverse and longitudinal frozen sections of tendon. Briefly, ultra-thin longitudinal sections, which are not as difficult to obtain as transverse cryosections, have already provided direct evidence for a prominent transverse periodicity larger than the unit cell dimensions in the hexagonal model of Hulmes and Miller<sup>26</sup> but compatible with the presence of an 80 Å structural unit.

Fresh rat tail tendon was fixed for 60 min in 2.5% glutaraldehyde at 4 °C, soaked for 45 min in 30% glycerol in water (which

acts as an antifreeze agent), dissected into small pieces (1 mm cube at most) and frozen rapidly by immersion in Freon 12 cooled by liquid nitrogen. The frozen tissue, held at about -110 °C, was sectioned, using an LKB ultramicrotome and Cryokit, with a glass knife at -45 °C, onto a trough containing 50% dimethylsulphoxide. Sections or section fragments (sections tended to tear because of the very fibrous nature of the tendon) were collected on formvar/carbon coated grids and either negatively stained with 2% ammonium molybdate or positively stained with 2% uranyl acetate and Reynolds lead citrate. In some preparations the initial fixation step in glutaraldehyde was omitted.

Electron micrographs of these various preparations often showed remarkably clear structure (as in Fig. 1*a*); they were comparable to or better than the best published micrographs of negatively stained or positively stained isolated fibrils obtained by homogenization (see for example refs 33 and 34). Stereo-pair electron micrographs also showed that in many of these preparations only surface negative staining was present and in such cases, despite the low inherent contrast, there was a considerable enhancement of detail and clarity. In addition to the marked *D*-periodicity along these fibrils (*D* in Fig. 1*a*) many seemed to show some evidence of transverse structure. They were frequently very fibrous in appearance, as noted previously by others<sup>33,34</sup>, but optical diffraction analysis showed little tangible trace of any equatorial spacings (other than diffuse and

**Fig. 2** Schematic ray diagram of the convolution camera<sup>10,11</sup>. The lamp and ground glass (or opal glass) screen provide an extended diffuse light source which evenly illuminates a transparency (*A*) of the micrograph to be studied. An identical transparency (*B*) at a distance *x* from *A* is positioned close to a lens which is set to focus parallel light in the plane of the film (right). The film is conveniently held in a reflex camera body. While viewing the image in the focal plane using the camera viewfinder, the transparency *B* is rotated in its own plane until the images in *A* and *B* are exactly parallel. This can be judged by making the central spot in the image plane as small and symmetrical as possible. When this has been done, the image is the self-convolution of the micrograph in *A* (or *B*). The ray diagram illustrates the light paths for a model micrograph containing three equidistant transparent objects (here shown as holes). Each hole in *B* acts as a pinhole camera and transmits light from *A* to form an inverted image of *A* in the film plane. But since the holes in *B* are periodically displaced, so are the images of *A* in the film plane. It will be seen that the central feature in this plane has light reaching it from each hole in *A*; it is an average of the features in *A*. Similarly further rays reach the film on each side of the centre and are separated from the centre by the periodicity in *A* (or *B*). Thus the self-convolution is a particular form of average of the structure in *A* (or *B*) and any regularities in the micrograph tend to be enhanced in the self-convolution. If *x* = *f* then the convolution has the same magnification as the micrograph, otherwise the magnification is *f*/*x*. Note that *f* is the focal length of the lens and must be fixed, whereas *x* can be varied at will. Full details of the convolution technique will be given elsewhere (ref. 12 and manuscript in preparation).

**Fig. 3** *a*, *c* and *e* are electron micrographs of collagen fibrils which were *a* fixed and negatively stained; *b*, unfixed and negatively stained and *e*, fixed and positively stained. The self-convolution functions of the outlined areas are shown in *b*, *d* and *f* respectively. In each case the whole self-convolution is shown at the top and just the central region is shown at the bottom. In *b* and *f*, the lower prints are at twice the magnification of the upper prints. Note that the whole outlined areas in *a* and *e* were used to give *b* and *f*, but that in *c*, the central light band in the outlined area on the convolution negative was blacked out using Indian ink (without doing this the light from the highly transparent but, in negatively stained preparations, relatively structureless overlap regions tends to swamp the convolution and to obscure the features of interest in the gap regions). The convolution in *d* therefore reveals the structure of the dark bands only. Clear lateral periods can be seen in *b*, *d* and *f* and the spacings measured from these were respectively,  $s = 75\text{--}80 \text{ \AA}$  ( $D = 583 \text{ \AA}$ ),  $s = 95\text{--}100 \text{ \AA}$  ( $D = 625 \text{ \AA}$ ) and  $s = 55\text{--}60 \text{ \AA}$  ( $D = 598 \text{ \AA}$ ).

unmeasurable regions barely perceptible above the noise level) out to a reciprocal spacing of about  $1/20 \text{ \AA}^{-1}$ . However, similar negative results using optical diffraction have been obtained from other fibrous protein structures such as isolated paramyosin filaments<sup>10</sup> and synthetic tactoids of tropomyosin<sup>11</sup>. In both cases some trace of a transverse periodicity seemed to be apparent from visual inspection, and despite the failure of the optical diffraction method, the existence of a strong lateral periodicity (about  $35$  to  $40 \text{ \AA}$  in each case) was confirmed by means of the so-called convolution camera<sup>10,11</sup>. In this camera (Fig. 2) the self-convolution function (or auto-correlation function) of an image is generated by a simple optical system<sup>10-12</sup> comprising a diffuse light source, two identical negative transparencies (A and B) of the image to be analysed, a lens and a film holder. If periodicities are present in the micrograph, then they will become very much enhanced in the self-convolution. The extent of the order can also be deduced. Just like the Patterson function in X-ray crystallography, to which it is analogous, the self-convolution function reveals the presence of strong inter-object vectors in the image being studied.

Application of the self-convolution technique to collagen fibrils such as that in Fig. 1*a* has revealed directly that a strong transverse periodicity is often present. Other examples are shown in Fig. 3. The spacing of the periodicity was in each case related to the  $D$ -period of the same fibril which in turn was deduced from the known calibration of the electron microscope. It was found that the  $D$ -spacing varied between different preparations and even between different fibrils in the same electron micrograph, the observed  $D$ -spacings generally being in the range  $580\text{--}710 \text{ \AA}$ . A wide variation of this period as a function of moisture content has previously been observed in X-ray diffraction studies of tendon<sup>35</sup> and presumably this behaviour is

being mimicked here by a variable stain content in our preparations.

It can be seen in the self-convolution in Fig. 1*b* that there are strong regularly spaced lines of density (white) running parallel to the fibril axis in Fig. 1*a*. Similarly in Fig. 3*b*, *d* and *f* it is clear that the lines running from left to right (that is, perpendicular to the fibril axis) are composed of discrete blobs of density (white) with a fairly uniform spacing. These appearances are direct evidence that there is regular transverse structure within the fibrils which gave rise to the convolutions. However it was found that not all fibrils or even all areas of the same fibril gave equally regular convolution patterns. But, whenever the lateral periodicity could be seen clearly, it always had a measured spacing ( $s$ ) of about the same size. Most of the fibrils which were studied were from fixed and negatively stained preparations (for example Figs 1*a* and 3*a*) and the observed range of side-spacing was  $s = 55\text{--}80 \text{ \AA}$ . Preliminary examination of unfixed fibrils (Fig. 3*c*) or fixed positively stained fibrils (Fig. 3*e*) has given  $s$  values of about  $90\text{--}100 \text{ \AA}$  and  $55\text{--}60 \text{ \AA}$  respectively.

Despite the apparent lack of order in some fibrils, it is clear in others (for example Fig. 3*a*) that the order is very good. In some cases the transverse order has been seen up to eight to ten  $s$  periods from the centre of the convolution, indicating a correlation of lateral structure over a range of about  $500$  to  $800 \text{ \AA}$ . This would represent most or all of the width of many collagen fibrils<sup>24,25</sup>. Similarly the presence of obvious structure along the strong transverse lines above and below the central line through a convolution such as Fig. 3*b*, shows that the lateral structure in one  $D$ -period correlates well with that in the adjacent  $D$ -periods along the fibril. We have observed similar correlation over an axial range of at least four  $D$ -periods, indicating that in some preparations there is a very high degree of structural regularity.

along the fibrils. It is not yet clear whether the observed differences in regularity within or between fibrils are a result of the preparative procedure, or are an inherent feature of the fibrils *in vivo*.

The observation of a transverse periodicity of 55–100 Å implies that there is some form of molecular organization of intermediate size within collagen fibrils; this, clearly, is incompatible with the model of Hulmes and Miller<sup>26</sup> as it stands. Recently Bailey *et al.*<sup>36</sup> have also questioned the validity of this model on the basis of cross-linking data. On the other hand our results tie in well with the observations of Parry *et al.*<sup>24,25</sup> on fibril diameters and they are consistent with the presence of an 80 Å molecular aggregate. However, it remains to be seen whether the molecular organization takes the form of microfibrils as previously described<sup>1–9</sup> or is related to some form of superlattice structure based on an underlying quasi-hexagonal lattice<sup>37</sup>. Although the observed variability in the side spacing could be due to variable distortion of a single structural repeat, it could also be a result of viewing a superlattice structure along different lattice planes.

In order to clarify some of these points, we are carrying out a further analysis of longitudinal cryosections of tendon and we also hope to develop the transverse cryosectioning technique so that the transverse ultrastructure of collagen fibrils can be seen in two dimensions. In the mean time the early results reported here provide direct support for some form of intermediate molecular aggregate within collagen fibrils and they emphasize once again the power of the convolution camera in studying elusive features in the transverse structure of fibrous protein assemblies.

We thank Dr D. A. D. Parry for suggesting this project, and the SRC for a project grant.

## Salt-dependent dynamic structure of poly(dG-dC) . poly(dG-dC)

Jean Ramstein & Marc Leng

Centre de Biophysique Moléculaire, CNRS, 1A, avenue de la Recherche Scientifique, 45045 Orléans Cedex, France

Until recently, all known nucleic acid duplex helices were thought to be conformationally related to A DNA or B DNA, these right-handed helices being characterized by C(3') *endo* or C(2') *endo* pucker for the respective sugar residues and by an antiligandic bond<sup>1</sup>. This situation has since drastically changed, for X-ray studies on crystals of alternating d(CpG) DNA fragments have demonstrated the existence of a left-handed double helix, termed Z DNA (ref. 2). In this novel double helix the base-pairing is of Watson-Crick type, but the cytidine and guanosine residues have the *anti* and *syn* conformations, respectively, and thus the repeating unit is two base pairs. Such a left-handed helix can also account for the X-ray diffraction pattern of alternating poly(dG-dC) . poly(dG-dC) fibres<sup>3</sup>. However, Pohl and Jovin have shown that in solution poly(dG-dC) . poly(dG-dC) undergoes a salt-induced cooperative transition<sup>4</sup>. It is very likely that the left-handed double helix is relevant to the high-salt conformation of poly(dG-dC) . poly(dG-dC) and that the low-salt conformation of poly(dG-dC) . poly(dG-dC) belongs to the B-DNA family<sup>3,5</sup>. The techniques previously used to study the salt-induced transition of poly(dG-dC) . poly(dG-dC) in solution—circular dichroism (CD), absorption spectroscopy<sup>4</sup> and nuclear magnetic resonance<sup>5</sup>—give essentially a static picture of the conformation of the molecule. Such information, although fundamental, is incomplete because double-helical nucleic acids in solution are known to be subjected to thermal fluctuations resulting in transient conformations with opened base pairs<sup>6,7</sup>. A particularly useful probe of the dynamic aspects of nucleic acid structure is the tritium exchange technique largely developed by Englander and colleagues<sup>10</sup>. We have now used this technique to study the dynamic structure of poly(dG-dC) . poly(dG-dC) and have found that this varies depending on whether high or low salt conditions are used.

The exchange rate of the five protons involved in the hydrogen bonds between guanosine and cytosine residues in poly(dG-dC) . poly(dG-dC) were measured at two different ionic strengths (1 M NaClO<sub>4</sub> and 3 M NaClO<sub>4</sub>). As Fig. 1 shows, there is dramatic difference between the two hydrogen exchange curves, the overall exchange in high salt conditions being much slower than in low salt conditions. In 1 M NaClO<sub>4</sub>, four protons are measured and they all exchange with the same rate characterized by an exchange half-time of 6 min. Identical results were obtained by Teitelbaum and Englander for poly(rG) . poly(rC) in the same pH conditions<sup>7</sup>. These four protons were assigned to the exocyclic amino protons of the guanine and cytosine whereas the missing proton corresponds to the guanine imino proton, whose exchange rate is too fast to be measured by this technique<sup>7</sup>. In contrast, all five protons of the (GC) hydrogen bonds are measured in 3 M NaClO<sub>4</sub>. The exchange of two of these protons is surprisingly slow, the exchange half-time being about 7 h. Subtraction of these protons from the total exchange curve reveals that the remaining three protons have the same exchange half-time of about 20 min (Fig. 1 inset). To rule out any possible effect of the difference in NaClO<sub>4</sub> concentration on the chemistry of the exchange process, we have studied the exchange in 2.5 M NaClO<sub>4</sub> of poly(dG-dC) . poly(dG-dC) trapped in its low-salt conformation (this is possible because the kinetics of the transition between high and low salt conformation is very slow, with a relaxation time of 2 h in 2.5 M NaClO<sub>4</sub> (ref. 3)). All the measured points fall on the exchange curve obtained in 1 M NaClO<sub>4</sub>, showing clearly that there are no measurable salt effects on the chemistry of the exchange process.

**Fig. 1** Hydrogen-tritium exchange curves at 0°C for poly(dG-dC). poly(dG-dC) (PL-Biochemicals, lot 658-5) in 3 M NaClO<sub>4</sub> (●), 1 M NaClO<sub>4</sub> (○) and 2.5 M NaClO<sub>4</sub> (▲). The salt solutions were adjusted to pH 7.5 and phosphate buffer pH 7.5 then added to a final molarity of 10 mM. It was checked that the CD (circular dichroism) spectrum of poly(dG-dC). poly(dG-dC) in 1 M NaClO<sub>4</sub> was almost an inversion of the one in 3 M NaClO<sub>4</sub>, in agreement with previous results<sup>4</sup>. The tritium Sephadex method of Englander was used<sup>10</sup>. All exchange experiments were carried out at 0°C. Exchangeable protons were labelled with tritium by incubating 0.5 ml of the nucleic acid solution (2 mg ml<sup>-1</sup>) with tritiated water (10 μl, 1 Ci ml<sup>-1</sup>) for 21 h. In all experiments the incubation solvent was identical to the exchange solvent except for the exchange experiment in 2.5 M NaClO<sub>4</sub>, for which the incubation solvent was 1 M NaClO<sub>4</sub>. To initiate the exchange of nucleic acid-bound tritium the incubation sample was passed through a Sephadex column (G-25 fine grade, 8 cm × 1 cm) previously equilibrated with the exchange buffer. This column removed the free tritium and the nucleic acid peak was collected in a test tube. To measure the amount of tritium still bound at any given time *t*, 300-μl aliquots were passed through a second Sephadex column (G-25 fine grade, 5 cm × 1 cm) previously equilibrated with the exchange buffer. This column removed the tritiated water formed during time *t*. The nucleic acid peak was collected in four test tubes which were analysed for radioactivity and nucleic acid concentration. The latter was determined by optical density at 260 nm, using a Zeiss PMQ II spectrometer and an extinction coefficient of 7 × 10<sup>3</sup> and 6.3 × 10<sup>3</sup> mol<sup>-1</sup> cm<sup>-1</sup> in 1 M and 3 M NaClO<sub>4</sub>, respectively<sup>4</sup>. Tritium was measured in 0.5-ml aqueous samples with 6 ml of dioxan-based liquid scintillation mixture by counting in an Inter technique SL 30 liquid scintillation counter. From the ratio of tritium counts per base pair, protons remaining unexchanged at *t* can be evaluated<sup>10</sup>. The gramme-atom concentration of protons in water was not corrected for the presence of NaClO<sub>4</sub> and was set equal to 111. For measurements of early time points (*t* < 5 min), a one-column procedure was used<sup>10</sup>. The exchange of the nucleic acid-bound tritium was initiated by passing 0.2 ml of incubation solution half-way down a column (8.5 cm × 1 cm). The flow was stopped to allow exchange to take place in the column during a suitable time interval; elution was then continued to complete separation of labelled nucleic acid and newly exchanged tritium. Fractions were collected and assayed as above. All necessary time corrections as indicated by Englander<sup>10</sup> have been made.

It is not possible to decide whether the two protons are the cytosine or the guanine amino protons, although the latter are the more likely candidates. Indeed, X-ray crystal studies of d(GpC) oligonucleotides show that a hydrogen bond is formed between the guanine amino group and a water molecule which is also hydrogen bonded to a phosphate oxygen<sup>2</sup>. Whatever the exact assignment of these five protons, our results show clearly

that the exchange rate of the protons is dependent on the conformation of poly(dG-dC). poly(dG-dC), which in turn means that the dynamic structure of the high and low salt conformations must be different.

Finally, we emphasize that this technique might be very useful for detecting the presence of the poly(dG-dC). poly(dG-dC) high-salt conformation in natural DNA. As already pointed out with respect to hydrogen exchange, the high-salt conformation is essentially characterized by the presence of two very slowly exchanging protons with a half-time at least 50 times greater than that measured for protons in double-stranded polynucleotides<sup>6,7</sup>. The existence of these two protons together with the high sensitivity of the tritium-labelling technique should enable the presence of small amounts of high-salt poly(dG-dC). poly(dG-dC) conformation to be detected in natural DNA.

We thank Professor C. Hélène for his interest and encouragement throughout this work and Dr E. Sage for her help. This work was supported in part by the Delegation Générale à la Recherche Scientifique et Technique (contract 79-7-06641).

## Neutron diffraction identifies His 57 as the catalytic base in trypsin

A. A. Kossiakoff & S. A. Spencer

Biology Department, Brookhaven National Laboratory, Upton, New York 11973

The mechanism of action of trypsin and other serine proteases has been widely debated<sup>1-5</sup>, particularly with regard to the identification of the group at the active site which functions as the chemical base during the catalytic process. Attempts to resolve this question by a number of indirect techniques, including NMR, isotope exchange, difference IR and quantum mechanical calculations, have resulted in different identifications of this group<sup>6,7</sup>. Neutron diffraction, because of its ability to locate hydrogen atoms experimentally, offers the most direct way of resolving this issue. Results are presented here from a 2.2-Å neutron data set for bovine trypsin covalently inhibited by a transition-state analogue, the monoisopropylphosphoryl (MIP) group. His 57 is clearly identified as the base in the catalytic process.

The catalytic site of the serine proteases is characterized by three invariant residues, a histidine (57), an aspartic acid (102) and a serine (195). The mechanism by which these enzymes hydrolyse peptide bonds can be described as a general base-catalysed nucleophilic attack on the carbonyl carbon of the substrate by the hydroxyl oxygen of Ser 195 (refs 8, 9). Coincident with this attack, the hydroxyl proton of the serine is transferred to the imidazole of His 57. The primary unresolved mechanistic question has been whether His 57 is the actual chemical base in the hydrolysis reaction (intermediate 2, Fig. 1) or whether the histidine acts as an intermediary through which Asp 102 functions as the base (intermediate 1). The neutron studies of myoglobin by Schoenborn and his co-workers<sup>10-12</sup>, which have shown that well ordered hydrogen and deuterium atoms can be located in Fourier maps of approximately 2.0 Å resolution, suggested that neutron diffraction would be the most direct technique to resolve the question.

The trypsin used in this study was initially inhibited with diisopropylfluorophosphate, an inhibitor which specifically and

**Fig. 1** The two different locations proposed for proton H-1 in the tetrahedral intermediate (TI) structure. In the formation of TI(1), H-1 shifts from  $N^{\pi}$  to Asp 102 ( $O-\delta 2$ ) as proton H-2 transfers from the serine hydroxyl group to  $N^{\pi}$  of the imidazole. His 57 remains neutral throughout the reaction. In TI(2), proton H-1 remains on the imidazole as H-2 transfers. The imidazole becomes charged and forms a zwitterion with the carboxylate of Asp 102. The intermediate pictured here corresponds to that formed during acylation and differs from the deacylation intermediate (which MIP mimics) only by the replacement of the leaving group ( $R_0-NH_2$ ) with a hydroxyl group.

covalently binds to the hydroxyl group of Ser 195 in serine proteases<sup>13</sup>. However, it was determined both chemically and crystallographically (R. M. Stroud, personal communication) that during the period of crystallization, this triester hydrolysed to the more stable diester form, producing MIP trypsin (Fig. 2). The geometry of this inhibitor closely resembles that of the tetrahedral intermediate<sup>14</sup>, which is believed to be the transition-state configuration for the hydrolytic reaction<sup>15-17</sup>. Analysis of this complex consequently allows the direct determination of the protonation states of the catalytically important residues at the crucial step in the hydrolysis.

Neutron data to 2.2 Å were collected at the single-crystal station at the Brookhaven High Flux Beam Reactor<sup>18</sup>. The

crystal of bovine trypsin was grown from  $MgSO_4$  at pH 7 (ref. 14) and had a volume of 1.5 mm<sup>3</sup>. It was soaked for approximately 1 month in  $D_2O$  solution containing 8%  $MgSO_4$  (pD 6.2, uncorrected) to replace most of the exchangeable hydrogen atoms with deuterium. This exchange greatly reduces the background component in the data produced by the large, incoherent scattering effects of hydrogen. In all, 8,700 independent reflections were collected using normal-beam rotation geometry. The initial phasing model was calculated by applying the appropriate neutron-scattering lengths<sup>19</sup> to the refined trypsin X-ray coordinates of Chambers and Stroud<sup>20</sup>. The first structure-factor calculation for the neutron data, excluding all hydrogen atoms and water molecules, gave an  $R$  of 0.304. The current model is refined to an  $R$  of 0.187. Table 1 summarizes the structure refinement statistics.

**Fig. 2** Schematic diagram showing the orientation of the MIP group with respect to the imidazole of His 57. The MIP group resembles the deacylation intermediate of the reaction. In the real intermediate, the phosphorus is replaced by a carbon atom and oxygen O-1 by a hydroxyl group. Ligand R corresponds to the amino acid side chain, which in MIP is an isopropyl group. The individual charges on the atoms in the MIP group are given<sup>25</sup>. The numbers in parentheses represent the computed differences in charge between corresponding atoms in the MIP group and the tetrahedral intermediate. The charges for the tetrahedral intermediate were obtained from a model reaction study (using methoxide ion and formamide) of the acylation step of the reaction<sup>26</sup>. The charge on the hydroxyl group was assumed to be approximately the same as that on  $NH_2$  in the methoxide-formamide intermediate<sup>27</sup>. Electrostatic potential energies were calculated using the expression  $E = \sum (q_i q_j) / (\epsilon_0 r)$ .  $\epsilon_0$ , the dielectric constant, was 3.0;  $r$  is the distance between charges  $q_i$  and  $q_j$ .

As a major objective was to identify conclusively the group acting as the base, it was necessary to ascertain that the identification of the proton positions in the catalytic site was unambiguous. Three methods were used to test the preferred location of proton H-1 (Fig. 1). In method 1, the deuterium (proton H-1 was exchanged for deuterium during the soaking procedure) was omitted from the model and the full structure refined through one cycle of coordinate shifts and model reidealization. This refinement cycle was run to eliminate any bias in the phases that might have been introduced by a previous placement of this atom in the model. As seen in Fig. 3a, the difference synthesis calculated from these structure factors shows a distinct preference for the deuterium to reside on the imidazole.

In method 2, a deuterium atom was placed by stereochemistry on the  $\pi$  nitrogen of the imidazole and its position refined. After two cycles, the deuterium exhibited stable refinement characteristics and a relatively low temperature factor, indicating that it was tightly bound to the parent  $N^{\pi}$  atom. This process was then repeated with the deuterium placed in the proposed alternative position on the O-δ2 of the Asp 102 side chain. In this case, the refinement was quite unstable, and the deuterium atom

\*Model contained no hydrogen or deuterium atoms.

† About three-quarters of the total hydrogen/deuterium atoms were located. 55 water molecules were also located and included in the phasing model.

‡ The current model is highly constrained, with r.m.s. deviations of bond lengths <0.015 Å and angles (bond and dihedral) <2.6° from the ideality. Nonbonded energy terms (van der Waals attraction-repulsion forces, electrostatic and torsional energies) have been refined.

**Fig. 3** *a*, A difference map  $((F_o - F_c) \exp(i\phi_o))$  calculated with only the deuterium (H-1) between the His 57 and Asp 102 side chains left out of the phases. The difference peak is approximately  $5.5\sigma$  above the background level and shows the deuterium to be bound to the imidazole nitrogen. *b*, A Fourier map computed with terms  $(2F_o - F_c) \exp(i\phi_o)$ . In this map, both of the catalytically important deuteriums (corresponding to H-1 and H-2 in Fig. 1) were omitted from the phases. This map clearly shows that both are located on the imidazole. (Hydrogen atoms appear as negative density because of their negative neutron-scattering length. The peaks for the ring hydrogens seem to be displaced from their true positions due to the limited resolution of the map. At  $2.2 \text{ \AA}$ , a portion of the negative density peak of a ring hydrogen overlaps the positive peak of the parent atom, effectively cancelling density between the atoms and giving the illusion that the peak has been translated.) *c*, A difference map in which the deuterium was placed by stereochemistry on atom O- $\delta_2$  of Asp 102 (if there were a proton coordinated to Asp 102, it would be on O- $\delta_2$ ). The difference density peak clearly indicates that the preferred location of the deuterium is on the imidazole of His 57.

resided along a distinct gradient, giving a clear indication of misplacement.

Method 3 involved the qualitative examination of two independent difference maps. For the first map, structure factors were calculated with the deuterium atom on the N $^{\pi}$  of His 57. In agreement with the refinement results, a nearly featureless map was produced, signifying that this placement was in close accord with the data. In contrast, placement of the deuterium on the O- $\delta_2$  of Asp 102 resulted in the interpretable difference map shown in Fig. 3c. The difference peak clearly indicates that a substantial shift towards the imidazole ring is warranted.

The results from each of these three techniques independently support the conclusion that the mechanistically important proton is coordinated to the imidazole of His 57. Taken together, we believe they offer compelling evidence that, at physiological pH, the protonated species in the tetrahedral intermediate is the imidazole of His 57 rather than the carboxylate of Asp 102.

To eliminate any possibility that the protonation states of the aspartate and histidine observed in this neutron diffraction study were artefacts due to the substitution of a MIP group for a real tetrahedral intermediate, a series of calculations was performed

to establish that the phosphate ester in trypsin also models the structure of the tetrahedral intermediate with respect to the location of the critical atom (H-1 in Fig. 1). Although both the phosphate ester (MIP) and the tetrahedral intermediate (TI) possess a net charge of  $-1$ , the centres of their charge distributions, with respect to the centre of the positively charged imidazole, differ somewhat ( $R_{\text{MIP}} = 4.3 \text{ \AA}$ ,  $R_{\text{TI}} = 4.6 \text{ \AA}$ ). However, energy calculations suggest that this difference of  $0.3 \text{ \AA}$  in the centres of the distributions is unlikely to be large enough for the MIP group to promote an interchange of the protonation states of His 57 and Asp 102 (from TI(1) to TI(2) in Fig. 1), as the calculated electrostatic potential energy (Fig. 2) derived from the interaction between the imidazole and the MIP group differs by only  $\sim 6\%$  from that obtained with a model of the expected tetrahedral intermediate.

Possible changes in the  $pK_a$  of His 57 were also explored by the method of Gurd *et al.*<sup>21,22</sup> Assuming no attenuation due to solvation, it was estimated that the MIP group can increase the  $pK_a$  of His 57 by, at most,  $0.8 \text{ pK}$  units, whereas the tetrahedral intermediate was estimated to increase it by about  $0.6 \text{ pK}$  units. In addition, the phosphoryl oxygen adjacent to the imidazole (O-1, Fig. 2), the largest contributor to the calculated  $pK$  effect, is solvent accessible; therefore, the influence of this oxygen should be significantly attenuated by solvation. If the assignment of  $pK$ 's by Hunkapiller *et al.*<sup>2</sup> were correct, the  $pK_a$  of His 57 would have to be raised by about  $3.0 \text{ pK}$  units to interchange the protonation states. As the calculated electrostatic effects due to the MIP group are much too small to accomplish this, it can be stated with confidence that the protonation states observed in the neutron diffraction experiment correspond to those in a true transition state.

The implications of the neutron diffraction results for the understanding of the mechanism of action of the serine proteases are twofold: (1) Those mechanisms which assigned Asp 102 as the base can now be eliminated from consideration and (2) the conclusive assignment of His 57 as the base will allow the major experimental emphasis of future work to focus on other important aspects of the mechanism. A more detailed description of the crystallographic results will be published elsewhere.

This research was carried out at Brookhaven National Laboratory under the auspices of the US Department of Energy. We thank Drs B. Schoenborn and J. Cain, who designed and developed the crystallographic station at the Brookhaven High Flux Beam Reactor, for their help and suggestions, Dr R. Stroud for donating the trypsin crystal and Dr J. Hanson for help with the computer graphics.

## BOOK REVIEWS

## Archaeologist extraordinary

Gordon R. Willey

V. GORDON Childe (1892–1957), an Australian by birth, who became, successively, the Abercromby Professor of Archaeology at the University of Edinburgh and the Director of the Institute of Archaeology at the University of London, was the foremost prehistoric archaeologist of his time. His influence on the archaeological profession, both in English-speaking countries and elsewhere, was profound and continues to be felt; and his best-known writings, although by no means "popular" in an ordinary sense, have been read in circles far beyond those of the profession.

Numerous articles, reviews and commentaries about Childe and his work have appeared over the years, but this study by Professor Bruce G. Trigger, of McGill University, is the first book-length intellectual and professional biography of this extraordinary man and scholar. Trigger is well-prepared for and suited to the task. As a Canadian he is familiar with both American and Old World archaeological histories, and his own research has spanned both archaeology and ethnology.

The biography begins with a brief consideration of Childe the controversial figure — "Man and Myth", as Trigger terms it — the conceptions and misconceptions about Childe that have developed in the archaeological community since the 1930s and 1940s and the publication of his two most widely read books, *Man Makes Himself* (Watts, 1936) and *What Happened in History* (Penguin, 1942). Trigger follows this with a review of European archaeology and archaeological thinking before Childe and indicates just how the latter both learned from and began to change this thinking. Subsequent chapters carry the story forward in time, although as the author's primary intention is to trace Childe's intellectual development there are, of necessity, many retrospective and anticipatory observations in his skilful analysis.

In such early works as *The Dawn of European Civilization* (Kegan Paul, 1925) Childe built on the artifact typologies and synchronisms of his predecessors, but he did it better, presenting the most complete and satisfactory synthesis of European prehistory up to that time. He accepted Kossinna's "archaeological culture" concept as a useful working device but rejected its racist grounding; while he abjured rigid unilinear evolutionism he

*Gordon Childe: Revolutions in Archaeology.* By Bruce G. Trigger. Pp.207. (Thames and Hudson/Columbia University Press: 1980.) £10, \$22.50.

Gordon Childe: "the foremost prehistoric archaeologist of his time".

then began his life-long attempt to develop a more sophisticated set of cultural evolutionary theories, doing so in conjunction with diffusionist thinking more akin to that of Montelius than to the extravagances of Eliot-Smith and Perry. This was followed up directly in the 1920s and 1930s with those great books, *The Danube in Prehistory* (Oxford University Press, 1929), *The Most Ancient East* (Kegan Paul, 1928), *The Bronze Age* (Cambridge University Press, 1930) and *New Light on the Most Ancient East* (Kegan Paul, 1934), all of which trace the course of development of Neolithic life and subsequent civilization from the Near and Middle East into Europe. In doing this, Childe's consideration of such processes of civilization as the stabilization of institutions, the widening of trade horizons, the capitalization of surplus wealth and the consolidation of smaller communities into urban settlements clearly foreshadowed present-day archaeological concerns. The same is also true of Childe's pioneer

settlement pattern studies in Scottish archaeology. Indeed, the last sentence of Trigger's biography sums this up forcefully and succinctly:

It is surely a measure of Childe's intellectual stature that, in spite of the buffeting of two decades, the major questions that he dealt with at the end of his career are now more critical to the future of archaeology than they were when he first raised them.

Here Trigger is referring primarily to some of Childe's later, more explicitly theoretical works of the 1940s and 1950s; but even in these earlier writings which were addressed to the data contexts of prehistory it is obvious that Childe had a sense of problem that overreached that of most of his contemporaries.

Childe is, of course, best known as a theoretician, and, cognizant as he was of the changing nature of the archaeological record, it was his own opinion that it was in this sphere that he would be best remembered; nevertheless, it cannot be overstressed that Childe was "data bound" in the very best sense of that term. This comes out, again and again, in all of his publications, as Trigger has demonstrated so tellingly. He was committed to the idea that the archaeologist should be concerned with the explaining of society, human behaviour and ideas, but he did not believe that this could be done successfully and satisfactorily out of the context of the facts of prehistory and history.

Much has been made of Childe as a Marxist thinker; but as Trigger shows us in his chapters "Human Progress and Decline", "Archaeology and Scientific History" and "Societal Archaeology", Childe was highly ambivalent about Marxist doctrine. Marxist dialectics presented to him a way of thinking, but there was always a tension, a conflict within himself as he measured the realities of the archaeological data in and on the ground with Marxist doctrines. In doing so he was cautious, critical, even pessimistic. He was a materialist but he was also a humanist. Out of these complexities and contradictions came the most creative archaeological writing of the mid-twentieth century.

No treatment of Childe would be, or could be, complete without some reference to the "new archaeology" of the 1960s and 1970s, and Trigger has provided this in a final chapter, "Beyond the New Archaeo-

logy". While Childe was not an immediate intellectual prototype for it, it cannot be denied that his writings have helped prepare the way. Childe was ever interested in the search for regularities, "laws" in human cultural and social behaviour. Trigger makes the point, however, that Childe differed from the "new archaeologists" in seeing human behaviour as changing, not immutable. In this he was Marxist for he believed that behaviour changed as social context changed. For him the search for "laws" was a legitimate but not the primary objective of archaeology. The primary objective and the future of archaeology lay, in his mind, with history — in the full context of social and cultural history. With this conviction, as Trigger says, he would have had little sympathy with archaeological examinations of "fragmentary" behaviour, behaviour out of context.

It is redundant or over-obvious to say that archaeology is "as large as life" — but, indeed, it is; or at least it may legitimately encompass all aspects of human life in the past. Gordon Childe was very much aware of this. Those who view him as a special pleader or partisan adherent of limited theoretical views overlook the facts of his devotion to and masterly control of the data, the traditional data of form, time and space. What he did was to ask new questions and in attempting to answer these questions — all of which were of importance in understanding mankind's past — he made us aware of how much of the potential record remained to be discovered. This was disturbing — and exciting — but it raised the discipline of archaeology to a whole new level of consciousness. □

Gordon R. Willey is Bowditch Professor of Mexican and Central American Archaeology and Ethnology at Harvard University.

## Red bed diversity

J.R.L. Allen

*Continental Red Beds. Developments in Sedimentology*, Vol. 29. By P. Turner. Pp. 562. (Elsevier Scientific: 1980.) Dfl. 145, \$70.75.

THIS is an important and original book in which the author sets out to synthesize and review what we currently know of the nature, depositional environments and processes, and diagenesis of continental red beds. Continental red beds and the "red-bed problem" have fascinated sedimentary geologists for many years, and in the minds of some investigators have seemed of particular petrogenetic significance. Dr Turner's book illustrates the variety of the issues raised by investigation of continental red beds and shows that it is

naïve to conceive of a single red-bed problem. Its value is rather to illustrate the remarkable diversity of continental red beds, a diversity of diagenetic environments and history as much as of depositional environment.

There are four sections in the book. The first considers the tectonic and climatic setting of ancient red beds and leads to a preliminary assessment of the question of the origin of red coloration. A practical classification of red beds is advanced, based on depositional environment, colour characteristics and diagenesis. The second and longest section is a thorough review of the depositional processes and environments of modern continental sediments and of ancient reddened counterparts, such as the European Lower Permian, the Upper Coal Measures of South Wales, and the Old Red Sandstone of the British Isles. The third section is concerned with the diagenesis, mineralogy and geochemistry of continental red beds. The fourth comprises two chapters, of which the first is a general account of the magnetization of continental red beds, and the second a study of magnetization case-histories (Proterozoic basins of western Canada,

Late Precambrian of Scotland, Moenkopi Formation of western USA, late Cenozoic red beds of Baja California). These clearly illustrate the complex controls on the magnetization histories of continental red beds and the difficulties of interpreting palaeomagnetic data, even when a wide variety of supporting field, petrographic and geochemical information is available.

Dr Turner's book is a carefully researched and well-written account of the sedimentology of continental red beds, the author moving confidently from large-scale phenomena to problems on the smallest of scales. The book was prepared from camera-ready typescript (there are a few small errors) and is well-illustrated by line drawings and photographs. There is an extensive and up to date list of references. The book is expensive but no sedimentologist concerned with continental sediments can afford to neglect it. □

J.R.L. Allen is Professor of Geology at the University of Reading. His research interests include the sedimentology of the Old Red Sandstone (a series of continental red beds of Devonian age) in southern Britain.

## Introduction to liposome research

Timothy D. Heath

*Liposomes in Biological Systems*. Edited by G. Gregoriadis and A. C. Allison. Pp. 424. (Wiley: 1980.) £23, \$69.

*Liposomes in Biological Systems* is the first book to be devoted completely to this aspect of liposomes. Its publication reflects the considerable expansion which has recently occurred in liposome research.

The book begins with a contribution by A.D. Bangham who traces the history of liposomes as he and others first characterized them, and their subsequent use by biologists. Following this, Dr Gregoriadis summarizes the potential applications of liposomes as drug carriers, and expresses his hopes for the future.

In the subsequent chapters various specialist authors concentrate largely on their own contributions to the field. J.H. Fendler describes the various factors concerned with encapsulation of drugs. G. Poste gives a critical review of liposome-cell interactions, which will enlighten those who may still believe the predominant mode of vesicle-cell interaction to be fusion. This area of liposome research in particular has been the subject of much recent reconsideration. Several chapters are devoted mainly to the *in vivo* fate of liposomes and their contents, including the uptake of enzyme-bearing liposomes by G. Weissmann and M. Finkelstein. G. Scherphof *et al.* have described their efforts to elucidate the interaction of

liposomes with serum components, and H. Kimelberg discusses his work on the *in vivo* fate of encapsulated methotrexate. I. H. Shaw and J. T. Dingle describe the interarticular injection of steroid-containing liposomes which is indeed one of the most promising applications of liposomes so far developed. (It would also have been appropriate had this volume included a chapter on the work of C. D. V. Black, R. R. C. New and C. R. Alving on the use of liposome-encapsulated antimonials in the treatment of visceral Leishmania, which clearly may be one of the first successful therapeutic applications of liposomes.) The final specialist chapter, by G. M. K. Humphries, covers the use of liposomes for studying *in vitro* immune reactions, which will undoubtedly become a major area of liposome research.

The contents of this volume are very similar to those of Vol. 308 of the *Annals of the New York Academy of Sciences* (1978), and most of the contributions appear to have been written between 1976 and 1978. The delay in publication is unfortunate, although Dr Gregoriadis has added a short chapter which summarizes much of the more recent literature.

In conclusion, this volume will provide a useful introduction for those unfamiliar with the field. □

Timothy D. Heath is a research fellow at the Cancer Research Institute, University of California, San Francisco.

# Telescopes of the future: heading for the supergiants

V.C. Reddish

*Optical and Infrared Telescopes for the 1990s.* Edited by Adelaide Hewitt. Two volumes, pp.1260. (Kitt Peak Observatory: Tucson, Arizona, 1980.) \$35 + \$15 airmail.

AT A time when the financial outlook for fundamental science may appear bleak, these two volumes should raise the spirits even of the pessimistic. Undaunted, more than 200 scientists and engineers gathered at Tucson, Arizona, in January 1980 to discuss how best to apply the latest technologies to the design and construction of very large optical and infrared telescopes, and what further technological research and development is needed for that purpose in the immediate future. This record of their deliberations makes exciting reading.

A wide range of possibilities was considered for telescopes with apertures mostly in the range 7m to 30m; the pros and cons of monolithic versus segmented mirrors, multi-mirror versus multi-telescope, single telescope versus arrays, were argued. Everyone, it seems, accepts that mirrors will be thin whatever configurations are adopted; the UK Infrared Telescope has proved that they can give optical performance and major cost savings.

Although various kinds of mountings were mentioned — alt-az, inverted alt-az, siderostat, steerable dish — not a lot of consideration was given to this aspect of telescope construction, and even less to the problems of domes and buildings. These are areas where major cost savings may be made and it could be worthwhile having a follow-up conference on the topic of housing very large telescopes. A radical breakaway from historical approaches (even recent ones such as the MMT building and the CERGA concept) may be possible and desirable if large economies are to be made, sufficient to make the construction of very large telescopes acceptable propositions. Do we really need to erect large concrete towers with rotating domes on top, or even rotating buildings, to protect the telescope from the weather and to provide a satisfactory working environment for engineers when it is not being used, and to shield it from the wind when it is? The cost is high not only in financial terms but in the deleterious effect which the building usually has on the astronomical seeing. I think that far more satisfactory structures could be made at costs one to two orders of magnitude less than those current.

A heartening feature of the discussions, however, was the recognition of the need to pay attention to the relationship between the design and aperture of the telescope, and the effects of the atmosphere on the image. These are of course functions of the

wavelengths at which the telescope is to be used and therefore relate to the astronomical research objectives and to the instrumentation — spectrometers and detectors — to be employed. This chain forms a recurring theme throughout the discussions; repeated attention was drawn to astronomical objectives and to the need to make the whole telescope system efficient. Considerable further advances in computer control are possible and substantial gains in efficiency can result from more extensive use of photoelectric autoguiders. It is surprising, as one participant pointed out, that autoguiders are still so little used. Every telescope built by the Royal Observatory Edinburgh since 1962 has been autoguided and that has been a major factor in the high quality of photographs produced by the UK Schmidt Telescope in Australia which was equipped with one from the outset; if it can be done for a Schmidt telescope, it can be done for any telescope.

There were so many contributions that it is impossible to mention more than a few. The experimental data on deformable mirrors by J.W. Hardy I found fascinating; also the discussion of (iso)thermally invariant structures by F.D. Drake and the paper on imaging by C.H. Townes. The most important technological papers, however, were probably those concerned with the matter stated succinctly by T.S. Mast and J.E. Nelson:

The central problem with a segmented mirror is to assemble the small mirrors and maintain their orientations and positions so they form the figure of a single large optical quality mirror.

## Between the sheets

J.M. Thomas

*Intercalated Layered Materials.* Edited by F. A. Levy. Pp.562. (Reidel: 1979.) Dfl.150, \$78.

WHEN a sheet-like structure assimilates guest species into its interlamellar spaces the phenomenon is known as intercalation. The uptake of ammonia by clay minerals in soil, first identified in 1850, is an example of such a process, so also is the swelling of clay when immersed in water, an effect known to the potters and ceramicists of antiquity. When transition-metal chalcogenides (such as niobium diselenide or molybdenum disulphide) take up alkali metals, the intercalation may dramatically alter the electronic properties of the parent solid: semiconductors become metals and metals semiconductors, purely as a con-

A telescope of today: the multi-mirror telescope on Mount Hopkins, Arizona.

Much effort, study and experiment will be devoted to this problem in many observatories around the world during this decade. It will be a happily competitive business, a race to be the first with the biggest and the best. It is difficult not to believe that the problem will be solved and the 1990s will see giant telescopes with apertures of 25m or more probing the outer half, the earlier half, of the Universe, intent upon discovering its structure, chemistry and evolution. The prizes in new knowledge in one of the most fundamental of our sciences could be immense, a just and proper reward for the supergiant telescope builders.

V. C. Reddish was until recently Director of the Royal Observatory Edinburgh and Professor of Astronomy in Edinburgh University. The UK Schmidt Telescope in Australia, the UK Infrared Telescope in Hawaii and the COSMOS measuring machine at Edinburgh were built under his direction.

sequence of the donation of electrons into empty or partially filled bands. Moreover, the addition of a wide range of organic materials (amines, amides, acids, pyrimidines and numerous heterocyclics and their derivatives) changes the superconducting transition temperature of the chalcogenide. When graphite, the best known and most widely studied of layered solids, assimilates certain electron-donating or electron-accepting guests, the process is accompanied by many significant structural, chemical and electronic changes. Alchemists would doubtless have been aroused to discover that when graphite is exposed to the vapour of potassium the glistening black solid is "transmuted" into a specular, golden mass. Intercalated species generally carry a residual charge and they usually take up

well-defined positions in directions parallel and perpendicular to the sheets. For graphite, but not, in general, for all other layered hosts, there is also the phenomenon of staging: the guests enter only some of the available interlamellar spaces and in an ordered fashion. The resulting range of structural possibilities is bewildering.

In this, the sixth volume in a worthwhile series devoted to the physics and chemistry of materials with layered structures, there are some outstanding chapters which elegantly combine both comprehensive coverage and critical assessment. All of the chapters are, to a greater or lesser degree, useful, but one or two lapse into the kind of language which scientists, in their quests for funding, inflict upon grant-awarding committees. Thus we read "... graphite intercalation compounds provide a near-ideal training vehicle in electronic materials science ... The frequent observation of surprising or dramatic results provides a beneficial stimulating effect, and the ever-present potential for gross error instills [sic] a healthy caution". Such sentiments could equally justify a reinterpretation of the Egyptian Book of the Dead or the factors that led to the emergence of Sufism.

Solid-state physicists, chemists and materials scientists will find much that is stimulating and rewarding in this monograph. I know of no more comprehensive survey of the intercalates of transition metal chalcogenide,  $\text{MX}_2$ , than that provided here by G. V. Subba Rao and Shafer, and no superior summary of the exciting developments that have occurred in studies of graphite intercalates since they were discovered by Schaufhault in 1841 than the chapter by Herold. The former deals admirably with, *inter alia*, the analogy between "solvated" intercalates (such as  $\text{Na}_x^+(\text{sol.})_y$ ,  $(\text{MX}_2)_x^-$  where solv. can be water, formamide, glycol, ethers, amines or amine oxides) and classical polyelectrolytes, well-known to colloid scientists. The latter covers all relevant aspects of graphite intercalate including two tentative schematic models for "interpenetrating stages" and "residue compounds" (where guest species are well and truly enclathrated up to quite high temperatures), the correctness of each of which has recently been confirmed by electron microscopic studies.

Ubbelohde's opening chapter summarizes his own well-known contributions to graphite intercalates, which receive further attention in this volume by M. S. and G. Dresselhaus, who review lattice mode structures explored principally by the Raman effect, and by Fischer, who assesses their electronic properties. Other chapters, devoted to chalcogenides, include an informative, closely argued contribution by Acrivos on the actual process of intercalation (its kinetic, mechanistic and thermodynamic aspects as well as likely bonding modes); a neat appraisal, by Beal, of the transition-metal intercalates of Group VA dichalco-

genides; a similar account by Rouxel of alkali-metal intercalates of hosts such as  $\text{MX}_2$ ,  $\text{MX}_3$  and  $\text{MX}_4$ ; and a rather telegraphic account by Samoana and Wollam of some intercalates of  $\text{MoS}_2$ .

The final chapter, entitled "Applications of Intercalation Compounds", by Whittingham and Ebert, though it covers thoroughly the electrochemistry of the various intercalates discussed elsewhere in this volume and touches upon the utility of variants of beta alumina as solid electrolytes and on  $\text{Li}_x\text{TiS}_2$  as typical, reversible, solid cathode material for commercially viable "solid-state" batteries, is rather brief in its attention to other chemical applications. True, when this book was written, which I estimate to be nearly three years prior to publication, not a great deal had been unearthed from the laboratory (or from existing literature!) about the range of chemical reactions that are "catalyzed" by various intercalates (for example the Fischer-Tropsch reaction and the ammonia synthesis). But it seems odd that, apart from the very last sentence in the book, there is no mention of one of the largest families of intercalates yet discovered — those formed by kaolinite, montmorillonite, hectorite and vermiculite. These so-called kandites and smectites form more or less stable intercalates with a wide range of polar and non-polar

molecules (including alcohols, hydrocarbons, amines, amino acids, ketones, purines and so on). Although the structures of these insulating, clay-based intercalates, are, with a few notable exceptions, no better elucidated than the structures of many of the intercalates discussed in this volume, what is abundantly clear is that the range of highly selective organic chemical conversions — dimerizations, etherification, lactonization, hydrogen transfer, ester and amine syntheses — that may be effected through their agency is already impressive and continues to grow. Recently, Weiss and others demonstrated that intercalated amino acids may be stimulated to produce peptides inside a sheet silicate, thus vindicating Bernal's well-known speculation about the role of clay minerals in the origin of life. Reflecting on these thoughts, one recalls that in the Biblical account of Creation the Hebrew verb "to form" in Genesis 2:7 is also the technical word used for the potter forming the clay into a vessel.

This book can be unreservedly recommended, despite a few minor errors such as the omission of many of the references given in the main text from the index of names. □

*J. M. Thomas is Professor and Head of the Department of Physical Chemistry at the University of Cambridge.*

## The biology of potassium

Clive Ellory

*Cell Potassium.* By Roderick P. Kerner. Pp.200. (Wiley-Interscience: 1980.) £17.30, \$40.65.

CONTROL of potassium, the dominant intracellular cation, is of fundamental interest and an obvious topic for a monograph. Appearing 15 years after its modest ancestor, *Cell K* (Butterworths, 1965), *Cell Potassium* is a more authoritative work, increased in breadth and depth. The author has retained the general framework, and certain figures and anecdotes are familiar (including the curiously obscure story about the *Discovery's* dredge of sharks' teeth). Plants and geology are discussed first, followed by a useful chapter on measuring techniques, which surprisingly omits any reference to micro-probe analysis. The author is clearly at his happiest dealing with nerve and muscle, providing a good account of anomalous rectification, action potentials and gating currents. The sodium pump is treated competently, at a level high enough to include the occluded K form and conformational states, but without some of the more byzantine complexities of this system (and, thank goodness, no mention of vanadate). LK cells receive flatteringly extensive treatment, which makes the omission of KCl co-transport in avian

erythrocytes and Ehrlich cells more surprising. Similarly, the Gardos effect gets short shrift.

Mitochondrial K movements and the chemiosmotic hypothesis are adequately covered, although a basic revision to refresh the amateur's memory on mitochondrial structure would be of value. This comment applies to other sections of the book; to some extent it appears to be addressed to the already informed, in that a working knowledge of the specific subject being covered is often assumed.

A short chapter is devoted to the important yet neglected role of K as a co-factor in many biochemical systems, before the book closes with a consideration of K in epithelial transport. Extended treatment of the Koefoed-Johnsen-Ussing model is tempered by discussion of other interesting epithelia like that of the cochlea, but the final brief chapter on interactions between body K and pH sits rather uneasily.

Nevertheless this is a scholarly work which, in the most fluent chapters, on excitable tissues, sets a high standard. With its unique thematic approach, it should serve as a useful reference work. □

*Clive Ellory is a Lecturer in the Department of Physiology, University of Cambridge.*

# Harvard backs off recombinant DNA

Harvard University's decision (see *Nature* 27 November) not to become a minority partner in a commercial venture to exploit recombinant DNA technology will have more than merely parochial consequences. Although it is probably no longer the case that universities in the United States and even elsewhere take their cues from what Harvard does, the public agony in which the university has come to its decision cannot fail to be instructive. Naturally, different universities will interpret events since the beginning of the term in October in different ways. Some will say that what has happened only goes to show that Harvard is the stuffy, or indecisive, place they have always supposed it to be. Others will be confirmed in their conviction that commerce does not mix with academic life. Harvard itself may be surprised to discover that the issue which it has been debating for the past two months has stirred up other and less tractable issues that will themselves keep both the administration and the faculty on tenterhooks for some time to come. What are the circumstances in which academic institutions may properly take a commercial interest in the academic research of members of their faculties? What limits should there be on the entrepreneurial interests of members of university staffs? And what arrangements do universities need for regulating these questions? Plainly there is a long agenda ahead.

The events of the past few months at Harvard are not without interest in themselves. The tale goes back to the beginning of this year, when small companies for the exploitation of recombinant DNA were springing up all over the place. One of the Harvard faculty, Professor W. Gilbert, was already a prominent member of the company called Biogen which held a press conference in Boston to make public its plans for using cloning techniques for the manufacture of interferon. Some of Gilbert's Harvard colleagues were even then disturbed at the implications of his involvement with a commercial company in such a prominent way. For although Harvard is probably more rigorous than most other distinguished universities in making sure that members of the faculty do not spend more than a limited proportion of their time on extramural activities, people were concerned that the work of one of their most creative colleagues (Gilbert shared this year's Nobel prize for chemistry) might in future be less freely shared within the university. The proposal that the university should become a minority shareholder (without paying for its shares) in a commercial company to exploit recombinant DNA techniques was at least in part inspired by the hope of doing the same thing while benefiting the university in some tangible way. The plan was that research carried out in Professor Mark Ptashne's laboratory should be exploited by a new company financed by venture capital, managed and housed separately from the university but from which the university would derive a substantial income. The university administration seems from the beginning to have been keen on the prospect of an alternative source of income. If it had seemed less greedy, the Faculty of Arts and Sciences might have been less quick to take fright. But, in the end, the proposal foundered on the faculty's misgivings. For a time, Cambridge (Massachusetts) seems to have been thick with anxiety about secrecy, academic freedom and the like, but perhaps the clinching argument against the commercial venture was that the university could not, in the arrangements proposed, avoid discriminating in favour of those on whose research its financial prospects seemed to depend. In a college of supposed equals, some would be more equal than others.

Such issues are familiar stimulants of cant, and even Harvard's

internal argument appears not to have been entirely blameless in this respect. Talk of academic freedom jeopardized would have been more persuasive if those professing concern for this lofty cause had been able to specify what specific freedom might be lost. It is also important to acknowledge that both Gilbert and Ptashne have been entirely open with their colleagues (and with outsiders) about their motives. Indeed, it is ironical that Ptashne, the latecomer in commercial matters, should now be widely identified with a project which the university has flirted with but dropped. Meanwhile, the serious questions the Harvard faculty has been asking about the entrepreneurial role of universities, or of members of their faculties, remain unanswered.

There is one important respect in which the issue is already decided. Since 1975 and the change in that year in the rules for the ownership of patents deriving from research carried out with research grants from the National Institutes of Health, Harvard (like other American universities) has become a substantial patent holder. The new rule is that universities can acquire the rights in patentable inventions arising within their laboratories if they can somehow persuade those responsible to apply for legal protection. Experience, not only at Harvard, has shown that little benefit accrues to anybody — the university or even the public — if a patent holder simply sits on his patent. Exploitation requires flair, finance and a keen sense for dollar bills (or for whatever other currency may be concerned). Even well organized universities in the United States are probably less commercially effective at making money out of patents than would be strictly commercial organizations. (In Britain, where the National Research Development Corporation is the public patent holder on behalf of academics and their universities, complaints are common that more might be done to make money out of people's cleverness.) In a sense, Harvard's proposed venture into biotechnology was merely an extension of its established role as a patent holder. On the face of things, moreover, the university was not being asked to back the new company with funds of its own. Yet there is a difference of principle between earning royalties on a set of patents and being a shareholder in a company. Substantial shareholders, however cheaply acquired their equity, must take a serious interest in the management of their companies — and must be prepared, when things go wrong, to step in quickly with extra funds. There is no reason to suppose that Harvard would be any more able to shoulder these responsibilities than other universities. Indeed, given the way in which at Harvard the administration's power of decision is rightly blunted by the veto powers distributed among the several faculties, Harvard is not everybody's favourite business partner.

There is also force in the argument, much canvassed in the past two months, that a university cannot enter into a risk-taking business partnership with some section of its own faculty without resolving the obvious difficulties in advance. Whatever the terms of the partnership, success is certain to engender a pattern of importance within the faculty that reflects considerations other than academic merit. Ptashne, no doubt, would argue that arrangements could have been made for avoiding such problems; a faculty as vigilant as that at Harvard is unlikely to have allowed the university administration to favour him and his immediate colleagues with extra space and resources, however successful the new venture. The more serious problems would have arisen if the venture seemed to be failing. Would it then have been possible for either partner to have behaved as if only academic business mattered? This is the sense in which joint involvement in a

commercial company differs from the sale and exploitation of patent rights, however profitable. The circumstances in which universities may properly set up commercial companies to exploit work of their faculty members are thus easily defined. Success must not depend on future promise, and there must be no foreseeable circumstances in which an academic will feel compelled to function as the research or even marketing director of a company if things should start going wrong. The academic freedom most at risk is that of the academics who are most directly involved.

A further difficulty, which persists even though the university has said no to its commercial venture, is that the laboratories of individual professors will continue to be sources of research with entrepreneurial potential. Even if Ptashne decides not to go ahead independently of the university, Gilbert as a member of Biogen will no doubt remain on the lookout for ideas that can be exploited commercially. No doubt he will be as anxious as his academic colleagues that he should never be open to the charge of making inequitable use of his position, and of his access to university facilities. The most immediate cause for concern must be the graduate students working in his and other people's laboratories. Graduate students are called students because the university to which they belong is responsible for their further education, and the formalities of registration for higher degrees reflect that understanding. There is, however, an obvious danger that in the present excitement about recombinant DNA, the Gilberts and Ptashnes of this world, but also their graduate students, will put commerce before education. Having said no to the university's proposal, the Harvard faculty now has no choice

but to make more explicit its corporate responsibility for graduate students.

In the long run, Harvard will find it necessary to take a further and more painful step. A university is a kind of club of academics, kept together by mutual respect. Academics' external interests are by no means always destructive of that spirit. Academics who serve their governments, who write good literature or who add to the public enlightenment in other ways, often by doing so enhance the esteem in which they are held by their colleagues and in which their university is held by the wider public. Naturally, most universities have explicit rules for making sure that academics are not so caught up in extramural activities that they have insufficient time for their students, but there are other less formal constraints to be reckoned with. The worst offence an academic can commit against his colleagues is to abuse his position as a member of his academic club.

Yet universities (like other kinds of clubs) differ in their unspoken definitions of what constitutes abuse. Even at Harvard, it seems to be accepted that within reason people should be able to advise commercial companies. The problem of the faculty member as entrepreneur in the exploitation of his own research seems not previously to have arisen as sharply as in the past few months. (At some other universities, it is commonplace.) The Harvard faculty seems to have been taken by surprise. It has only itself to blame for not having made its unspoken rules explicit long ago. What it needs now is a general understanding that people's extramural activities and the financial gains therefrom are fully disclosed within the faculty, and are proper material for faculty discussion and even decision.

## How not to run a public monopoly

The British government's proposals for the reorganization of the British Post Office (see *Nature* 27 November) seem calculated to win the worst of all possible worlds for everybody concerned, but the hapless users of telecommunications systems in particular. The chief purpose of the bill soon to begin its passage through the House of Commons is to separate the postal service from the rest of this nationalized industry, and there is no argument about the wisdom of that course. Indeed, for more than a decade the Post Office has been organized internally as if it were two organizations — a loss-making postal service and a money-making telecommunications service. Three years ago, Sir Charles Carter's committee on the problem told the government that it should go the whole way along this road, and formally split the two parts of the business. Everybody agrees that this should be done. But how?

The issue is important for several reasons, but not least because of the technical importance of the telecommunications industry to the wealth (and even the health) of a modern state. For far too long, Britain has been badly served by the electronic half of the Post Office. When other countries were installing modern and increasingly versatile telephone systems, would-be British users were forced to wait, often for more than a year, for the privilege of renting an antiquated handset. From time to time, bursts of excitement would nevertheless filter out of the British government's public relations network, explaining that this or that new miracle was about to be brought into service. In the late 1950s, for example, the "world's first" electronic exchange was being praised to the skies. Unfortunately, it never worked. More recently, with the new internal arrangements at the Post Office, there has been discerned a sense of realism. The managers of the telecommunications network have plainly begun to come to grips with the nature of their business. Keeping up with the Joneses (or the Japanese) technically is much more difficult than it seemed in the old days, when the Post Office would draft a specification for some new system and farm out the development and manufacture of the equipment to a cosy cartel of manufacturers. But the technical problems are not even half the battle. Managing a complicated telecommunications network is hair-raising.

Meeting the cost of developing a modern network is an exercise in high finance.

In all the recent discussions about the British Post Office, it has been plain that the crucial question to decide is where the line should be drawn between the public monopoly and private enterprise. Again, there is no dispute about the good sense of monopoly ownership and management of the telecommunications network. Every modern state has been driven to recognize as much. The questions that arise concern the definition of the monopoly at its margins, and the arrangements for its regulation. In Britain, there has been a lot of excited talk (encouraged by Sir Keith Joseph the industry minister) about the shading of the telecommunications monopoly. There are two respects in which this might with advantage be done. There is a need that those who rent access to telephone lines or other channels of communication should be allowed to attach to them whatever terminal equipment they choose, provided it is technically compatible with the network (and also legal). For no single organization, however competent (and British Telecom has a great deal of depressing history to live down), can hope itself to supply everything that users of the network are likely to need in the decades ahead. But the network (whatever it is) should also be usable by people prepared to offer services that the monopolists themselves choose not to offer.

Sir Keith Joseph's reorganization bill fudges both these issues. British Telecom will not have an exclusive right to supply all terminal equipment, but it will be dragged in if an attachment has to be serviced, while the minister's own civil service will assume some of the responsibility for telling what attachments can be attached. And yes, there will be arrangements for letting private people use the network for providing novel services, but again the details are not worked out and the minister's civil servants will again decide. The consequences of these un-Tory compromises are potentially disastrous. Neither British Telecom, the users of the network nor manufacturers of equipment will know where they stand, but crucial decisions about the development will return from whence they came several years ago — to the civil service.

# Anti-trust waiver for industrial research

## Justice blesses inter-company collaboration

Washington

The US Department of Justice has given the green light to research programmes jointly sponsored by two or more private companies, arguing that in general — and provided certain criteria are respected — these should not conflict with the country's strict anti-trust legislation.

Uncertainty about the implications of anti-trust laws is often cited by US business as an obstacle to greater cooperation in research. Their concern is that, once a joint research project has been agreed and set up, they may be accused of violating legislation developed to ensure maximum competitiveness between rival companies.

As a result, anti-trust legislation was closely studied during last year's domestic policy review of industrial innovation, carried out under the auspices of the Office of Science and Technology Policy (OSTP) and the Department of Commerce.

Announcing the results of this review last November, President Carter said that by spurring competition, anti-trust policies could provide a stimulant to innovation, but he added that in some cases — such as research — industrial cooperation might have clear social and economic benefits for the country.

"Unfortunately our anti-trust laws are often mistakenly viewed as preventing all cooperative activity", Mr Carter said. And, rather than proposing any change to the law, he instructed the Department of Justice to publish a guide explaining its interpretation of the laws that already exist.

The guide was finally published in Washington last week. It is now being closely studied by companies and research associations contemplating joint research ventures, since, although not a legally binding document, it indicates how the department is likely to react to particular arrangements.

The guide should also help to clear the way for the creation of so-called Cooperative Generic Technology (COGENT) centres. These have been proposed by the Department of Commerce and the National Science Foundation, jointly funded by government and various industrial companies in fields such as welding, lubrication and powdered metal processing. The idea was approved by Congress in recently passed legislation.

The guide points out that there are various ways in which joint research

ventures could involve anti-trust considerations. For example, they could lead to market-dominating technology, to unfair collaboration between commercial competitors or to restrictive agreements on the use of research results.

Each of these might restrict open competition. At the same time, the guide says, competitiveness is a source of increased innovation — while innovation itself is a basis for commercial competitiveness — so that to discourage the one is to discourage the other.

So the challenge is to develop an arrangement that will maximize the rate of innovation (and hence competitiveness) by permitting research that would not otherwise be carried out, but in a way that does not give one or more companies an

unfair advantage over others in the same field.

Rather than providing any hard and fast rules on how this should be done, the Department of Justice offers general guidance on how it would probably interpret existing statutes in particular situations. And it includes eight hypothetical case studies intended to illuminate its position.

As far as basic research is concerned, the department says that cooperation is unlikely to be much of a problem, since the competitive significance of the research is likely to be largely speculative and, as the results would be published in the open literature, there should be few problems about equal access by other companies.

David Dickson

## Science foundation all set at last

Washington

As widely expected, the US National Science Foundation (NSF) has announced its intention to set up a new directorate for engineering, and to distribute responsibility for applied science — at present administered jointly with engineering — across the foundation's basic science directorates.

Announcing the planned reorganization to members of the National Science Board last week, NSF's director-designate, Dr John Slaughter, said that creating the new directorate meant that the foundation intended to seek more resources for the engineering disciplines.

The reorganization is the result of discussions that have been taking place within NSF since early in the summer, and are partly in response to outside criticism that NSF has not been doing enough to encourage engineering research, with the result that engineering has suffered in comparison with more traditional basic science disciplines.

At the same time, NSF has dropped a proposal that had also been under discussion to set up a new directorate for social science, at present linked with the biological and behavioural sciences. Although many researchers had argued that such a move could help to enhance the academic status of social science research, administrators had voiced fears that it might increase the visibility of the social science research budget — and hence its vulnerability to congressional budget cuts.

According to Dr Slaughter, the new reorganization means that although basic research remains the central mission of NSF, the base of support for applied research will be broadened, since all research directorates will now support applied research projects while keeping their basic research programmes more or less in being.

In addition, the reorganization would

give new emphasis to engineering research and education, Dr Slaughter told the members of the National Science Board, which is formally responsible for the activities of NSF and had previously endorsed the reorganization proposals.

NSF officials hope that, by giving engineering research a new emphasis, they will be able to head off plans to set up a National Technology Foundation, contained in a bill introduced to the House of Representatives by Mr George Brown, chairman of the House Science and Research Subcommittee.

In a letter to Dr Donald Langenberg, acting NSF director, Mr Brown said that Congress might conclude, in studying the technology foundation concept, that "existing mechanisms to improve the state of technology are not able to handle current challenges, and that major programme dislocations are not too high a price to pay for a fundamental programme reorientation".

Several members of the engineering research community, while welcoming NSF's greater emphasis on engineering, have been saying that this will only improve the situation for engineering research, which now receives only about 10 per cent of the NSF's budget, if it results in more money being made available by Congress.

## Nuclear power

## Border problems

Brussels

France's policy of siting nuclear power stations on its frontiers has aroused antagonism both in the European Parliament and among environmental groups. The European parliament met on 19 November to discuss a report by Mechthild von Alemann (German, Liberal) which reflected the concern over the French government's plans to build

further power stations at Chooz and Cattenoom, close to the Luxembourg and Belgian borders.

The previous day, environmental groups from Luxembourg, France and Belgium had called a press conference in Luxembourg and denounced the French government's total disregard for the principles and rules of international law. The French, however, are not the only culprits. Of the 120 or so nuclear power stations at present in operation, under construction or planned in the European Community, 33 are less than 25 miles from national borders and another 15 are less than 6 miles from borders.

Von Alemann's report urges the introduction of Community safety norms and the implementation of a Community consultation procedure, bolstered by an EEC regulation. During the debate many speakers called for a broader interpretation of Articles 37 and 41 of the Euratom Treaty. These relate to the obligation of member states to supply the European

Commission with all data on radioactive effluent capable of causing pollution and details of all future plans for nuclear power stations.

French parliamentarians of all political hues united against the attack, claiming that it compromised national sovereignty. Pierre Calvez (French, Liberal) said he was opposed to any Community decision which transcended national policy. He added that all new power stations were subject to bilateral agreements and international regulations.

Speaking on behalf of the European Commission, acting Energy Commissioner Etienne Davignon declared that France had not infringed the Euratom Treaty and that the treaty could not be interpreted in such a light as to give the Commission the right to interfere.

Stanley Johnson (UK, Conservative) reminded the parliament of the fate of the so-called Sèvres Directive at the last meeting of the Environment Council in June. The draft directive on the prevention of major accidents was not adopted because the French objected to the provisions for transboundary notification procedures. A compromise formula over this problem is now being thrashed out and it is hoped that the next council meeting on 12 December will adopt the text.

The EEC's energy ministers, when they met in Brussels on 27 November, briefly discussed the problems associated with the siting of nuclear power stations near boundaries. The draft regulation on the Community consultation procedure for electricity power stations that affect the territory of another member state has been held up in the council for several years. It now seems likely that this regulation will be looked at more seriously and its progress accelerated.

### Soviet health

## More research

A high-level cooperation programme between Soviet scientists and doctors will be an important feature of the next Five Year Plan for public health. This was decided by a joint session of the Academy of Sciences and the Academy of Medical Sciences last month. An interdepartmental scientific council is to be established, and a joint research programme is being drawn up. This says Academician Anatolii Aleksandrov, president and chairman of the new council of the Academy of Sciences, will reflect the main problems in public health and take into account the potential of the country's scientific institutes.

Aleksandrov reported that cooperation between scientists and medical teams has already led to some major advances, including medical applications of ultrasonics, cryogenics and laser technology. The Minister of Public Health, Boris Petrovskii, spoke warmly of the raised standards of diagnosis and

treatment made possible by the introduction of new techniques in cardiology, oncology, surgery, paediatrics and pharmacology.

Molecular biology, which until the mid-1970s was neglected in the Soviet Union, received a glowing tribute from Dr. Nikolai Blokhin, President of the Academy of Medical Sciences. Recent results, he said, opened up prospects for the establishment of new ideas about the nature of viruses, malignant changes in cells, human heredity and the development of genetic engineering techniques. Other innovations are less welcome. The Marxist-Leninist world outlook, said Blokhin, protected Soviet medicine from mysticism, parapsychology, the psychosomatic theories of Freud, various types of neo-Freudianism and other "views that could lead medicine astray". He called therefore for greater cooperation between medical workers and representatives of the philosophical institutes of the Academy of Sciences.

### Polish science

## Advice not taken

The Gierek regime consistently "torpedoed or disavowed" constructive criticisms from its nine-person team of scientific advisers. So claims Professor Alojzy Melich, a member of the team since its inauguration in 1977, in an interview in *Trybuna Robotnicza*, the daily paper of Katowice (Mr Gierek's home power-base).

Professor Melich said that during the past three years, the team had prepared about a dozen comprehensive surveys on the main problems facing the country, as well as numerous smaller papers and analysis. These, however, were rejected by the government and the planning commission, simply because they attacked current policies. In the end, Professor Melich said, the government simply stopped providing its scientific advisers with any information at all.

This is not the first such accusation to be levelled in recent months. In August, an *ad hoc* farmers' committee which has since become the nucleus of the farmers' campaign for trade union representation, accused the authorities of suppressing expert reports on the deterioration of Polish agriculture. Unlike most critics, however, Professor Melich did not condemn Mr Gierek's policy of obtaining massive foreign loans to back his investment projects; these, said Melich, had provided an important stimulus for the economy.

The current economic crisis, however, has meant that the future of many major investment projects has become doubtful. Even the much hailed Programme-Wisla is liable to suffer some cutbacks at least for the present. This scheme, which was envisaged as a major contribution to Poland's economy in the twenty-first century, consists of a broad range of water-

### French take Manhattan

A French firm has stormed the US optical communications market — and installed a 6.5-km optical fibre system in Manhattan. CIT-Alcatel, the leading French telecommunications company, announced last week that it had beaten off competition — including the giant ITT — to supply the link to Western Union cable and telegraph company. They system will be the first fully operational optical fibre link in the United States CIT officials believe.

CIT will also supply the second such link, an experimental one which the company sold to Western Union a year ago. When the new link, which uses light emitting diodes to convert electrical signals into light, goes into operation in January, the experimental link (which uses laser diodes) will also be put into regular use. CIT will thus gain operating experience with the two principal competing technologies for optical fibre input.

The great advantage of optical fibre systems for Manhattan is that available cable ducts under the city are physically crammed to capacity, and it is now almost impossible to feed through standard electrical links. Optical fibre links, however, can be made on cables 10 times smaller in outer diameter — allowing a hundredfold increase in channel capacity for the same duct cross-section.

The CIT system uses cables, supplied by another company, of 1 cm outer diameter to carry 44 megabits per second (672 telex channels). CIT supplied the input-output devices and the data management systems for the link. CIT considers that this first step in the US market is "fundamental" and that the potential scale of the market is "huge".

**Robert Walgate**

## Cable of protest

One hundred and six Fellows of the Royal Society, including four Nobel Prize Winners, (Sir Nevill Mott, Sir Max Perutz, Sir George Porter, and Dr Fred Sanger) have sent the following telegram to the Soviet Delegation to the Madrid Review Conference.

"The arrest of Dr Brailovskii is a cause of great concern which can only harm further scientific exchange between our countries."

Viktor Brailovskii, arrested on 13 November, the day after the opening of the Madrid Conference, is thought to be facing charges under Article 191/1 of the Soviet Penal Code: Disseminating information known to be false and detrimental to the Soviet Union and socialist system. His detention, however, seems to be linked with his activity as host to the Sunday seminars for Jewish refusenik scientists in Moscow. Last week, his wife was warned by the security authorities not to try to go ahead with the seminar. When, on Sunday, she attempted to hold the seminar, intending participants were prevented by the police from entering the apartment.

In Washington last Sunday, the Committee of Concerned Scientists organized a seminar on the style of the Moscow seminar. A paper was read by Dr Maxine Singer who earlier this year was refused a visa to visit Moscow, where she had intended to visit the Brailovskii seminar. Several of the participants had read papers at the Brailovskii seminar during professional visits to Moscow. It is hoped to hold such seminars every Sunday in various US academic centres.

An international delegation of scientists, led by the French Nobel Laureate Andre Lwoff, who is a corresponding member of the Soviet Academy of Medical Sciences, is seeking a meeting with Ilichev, head of the Soviet delegation in Madrid, to discuss the Brailovskii case.

Vera Rich

managed developments, ranging from recreation to heavy transport, with canal links through the Soviet Union and East Germany. Such a major project cannot, of course, be simply abandoned, but as the press spokesman for the programme recently pointed out, it is a complex plan, the implementation of one part does not necessarily depend on that of another, and, in any case, the announced completion deadline of the year 2000 had rather "symbolic" significance. Nevertheless, he said, the country simply cannot afford *not* to implement some parts of the scheme as soon as possible — the anti-pollution and water-storage proposals which will be vital in the next few years if the country's agriculture and industry are to recover.

A similar stance was adopted recently in the *Sejm* (Parliament) by Deputy Zbigniew Kledecki. Speaking on the pollution of the

Krakow area by the Nowa Huta steel mills and the Skawina aluminium plant, he stated that the cost of installing modern, non-polluting equipment would be 120 million zloty (£2 million) at Nowa Huta and 7,500 million zloty (£125 million) at Skawina. Nevertheless, he said, in view of the grave pollution hazards and the "critical attitude of community scientists and journalists in Krakow", preparatory work on modernizing the plants would begin next year.

Important as such major investments still may be, the most immediate investment problem is that of agriculture. Recent pledges by the Minister of Agriculture, Leon Klonica, include an increase in the production of plant protection chemicals, and fertilizers, investments in land-improvement, development of an intermediate technology suitable for small farms, changes in the supply and pricing system to aid the private farmer, and a relaxation of central arbitrary planning in agriculture. These last points, which are a considerable reversal of recent policy, have been welcomed by the farmers with cautious approval.

Vera Rich

## Brazilian universities

### No cash ahead

Sao Paulo, November

Inflation and a lack of sympathy from the state government have forced the University of São Paulo (USP), Brazil's oldest university and one of its best, into a serious crisis. But the crisis is not confined to São Paulo. All government-supported universities face difficulties over dwindling budgets. Academics throughout Brazil have been protesting about the lack of resources by holding a series of one or two-day stoppages, the latest at the beginning of this month.

The academics' complaint is that the state and federal governments have made the universities take an unfair share of public expenditure cuts and have thus neglected the country's long-term future in the panic to service Brazil's massive foreign debt and oil import bill. This results in the universities having virtually no money for new building and very little for buying and maintaining equipment.

The most serious complaint, however, is the effect of inflation on academic salaries, which have recently been increasing at only about half the rate of inflation and which are corrected only once a year. (The academics are asking for termly readjustment.) The lack of money available for salaries has meant that some academics have to turn to part-time and piecemeal teaching. Many academics can get contracts for only 20 hours a week and have to eke out a living by other means. But even those with 40-hour contracts are finding it necessary to look for ways of topping up their incomes.

Salary problems seem to vary from one

university to another and depend on how individual funds are administered. Some federal universities, called *fundações*, are allowed to keep their own trust funds which are being used to top up salaries, but others, the *autarquias*, are strictly limited to paying agreed government salaries only. For those in the humanities in the *autarquias*, the outlook is bleak, but for scientists there is a chance of extra support from the national research councils, which have recently started to top up researchers' salaries as well as making research grants. The budgets of the research councils have not, however, stretched to helping every scientist worthy of support.

The number of applications made to the main research council, the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), for grants to supplement salaries increased dramatically in 1980. The CNPq estimates that it is now supplementing about 2,200 scientists' salaries and that its sister organizations may be supplementing as many as 3,000. Most notable, says the CNPq, is the large increase in applications from the University of São Paulo.

For federal universities, the CNPq is confident that the problem is only temporary and that the salaries problem will be alleviated by the beginning of the next academic year in March. The University of São Paulo, however, cannot necessarily expect such a reprieve. Its finances are controlled by the government of the state of São Paulo which allocates the budget annually — the most serious deterioration in the university's finances has occurred over the past few years, since a change in the state government.

If São Paulo has been hit more severely than most of the federal universities, it may be — according to one administrator — that the university had more to lose. But many academics and newspaper reports blame the crisis on the governor of São Paulo state, Paulo Maluf, who is keener on oil exploration projects than on the university.

The university's teachers' association says that its share of the state budget decreased from 3 per cent in 1975 to 1.89 per cent in 1980, and that the share taken by higher education generally decreased from 5.1 per cent to 3.3 per cent over the same period. The same figures put the average salary of a full-time professor at about 80,000 cruzeiros a month (£6,000 a year), less than half of its maximum real value in the past decade. But budgets are not the only problem afflicting Brazilian universities. Their rapid expansion from 500,000 students in 1968 to 1.5 million now has led to unwieldy bureaucracies which changes of government have only aggravated. At São Paulo, the seat of university unrest in 1968, academics say that even relatively small items of expenditure have to be approved by the rector, who in turn has to argue for funds with the state government.

## High-energy physics

# Machines shut down

A rise in electricity prices of nearly 50 per cent has forced the West Germany high-energy physics laboratory, DESY in Hamburg, to close down its accelerators until the end of 1980. The federal government in Bonn has asked the regional Hamburg government to foot the bill, but Hamburg refused — so DESY had to shut, losing three weeks of accelerator time.

Electricity costs have risen because of a recent agreement between the utilities, coal mining companies and the government. Under the agreement, coal used in electricity production will be raised from its present 33 million tonnes a year to 45 million tonnes by 1985. The utilities will thus have to invest in new power stations and the federal government has allowed them to raise the necessary cash from the consumer.

DESY will have to find another DM 5–10 million (£1–2 million) in 1981 to cover the increased electricity charges. If the money is not forthcoming, the accelerators will have to be run at two-thirds mean power. This would mean either low-energy experiments or relatively few runs at high energy. For example, Nobel laureate Samuel Ting's experiment to find interference between the weak and electromagnetic interactions, as evidence for the intermediate vector boson, requires the highest energies and long data runs and may be threatened unless one or other government pays the increased bill.

The federal government in Bonn, however, which through the Bundesministerium für Forschung und Technologie (BMFT) provides 90 per cent of DESY's budget, is in the red, and has been asking all public institutions to find savings. DESY's DM 143 million budget for 1980 has already suffered two cuts — DM 10.5 million in its DM 50 million "capital projects" budget (achieved by delays) and DM 1.5 million in running costs. BMFT also seems set not to grow this year, its provisional increase for 1981 being slightly less than the current 5.3 per cent annual growth in the cost of living in Germany.

In principle, the Hamburg government could increase its 10 per cent contribution to DESY, as it already benefits from DESY's policy of placing many of its equipment contracts with local industry, and it owns the electricity company which is now charging the laboratory so highly. So far, however, it has not done so.

The DESY crisis may prove to be a test of the new science minister's faith in basic science. Dr von Bülow announced at a press conference last week that he was in favour of "full government financing" for basic research, whereas in energy research, for example, industry must make a contribution.

In the long run, physicists have pinned DESY's future on the construction of

HERA, a DM 600 million machine to collide electrons with protons at high energy and so probe proton and quark structure; the project is being weighed against other big science projects by a committee of BMFT, and no doubt electricity costs will be taken into account. DESY's electricity bill this year will be about DM 22 million, with the full HERA, at current prices, about DM 43 million. So DESY is making a great effort to develop superconducting bending magnets for the proton ring to keep down the bill. It has two designs, one based on the successful dipole constructed at Fermilab in the United States and another under construction at Saclay in France.

Moreover, it is still planned to build HERA in two stages, the first involving 35 GeV electrons and positrons alone and costing DM 290 million. This stage could be ready 5½ years after approval (at the end of 1986 at the earliest) and still offers some competition for the large electron-positron ring (LEP), the next major project of the European nuclear research centre CERN at Geneva. LEP's electricity costs for the same energy would, however, be lower as its ring would be much larger, and it would radiate less synchrotron radiation (the major energy sink in a circular electron machine).

Robert Walgate

## Third World

# Consumers arise

Kuala Lumpur, November

At a time when the new Administration in the United States seems likely to ease up on the stringent regulation of technological products, consumer groups in the Third World are beginning to voice demands for protection against potentially harmful substances and goods like that already adopted by more affluent societies.

A principal target of such groups in the alleged "dumping" in developing countries of products, such as drugs and pesticides, which have been banned in one or more of the industrialized nations.

Three weeks ago, for example, individuals from twelve developing nations attending a conference in Malaya organized by the International Organization of Consumer Unions (IOCU) signed a declaration urging that there should be no distinction between domestic and foreign consumers in export control programmes for hazardous substances and production facilities.

But the concerns of the embryonic consumer groups in the Third World go much further, ranging from the conventional complaints about the quality of consumer goods to criticism of low-standard imitations of Western goods (for example a drug named "Panadol", easily confused with "Panadol").

Malaya's Finance Minister, Tangku Razaleigh Hamzah, has called on university scientists and other faculty

members to put their efforts behind work of such consumer associations, should be "watchdogs of the people veying the unfair practices of business".

Tengku Razaleigh was speaking at a seminar on economics and development organized by one of the largest and active of Third World consumer groups, the Consumer Association of Penang (CAP).

Formed more than ten years ago on a Malayan island of Penang, CAP now has a full-time staff of 60. Its activities cover a range of issues familiar to pressure groups in industrialized countries, from assisting fishermen whose livelihood was threatened by the discharge of wastes from a new factory, to working with local labour unions to identify occupational carcinogens, to developing courses and teaching materials on consumer rights for use in school and universities.

One of the successes claimed by CAP was the Malay government's decision to accept explicit responsibility for environmental issues by expanding its portfolio of the Ministry of Science and Technology. Various controls on pollution sources have since been introduced, but less progress has been made on efforts to curb the rapid exploitation of Malaya's diminishing natural resources. As with tin and petroleum, these include wood forests which may disappear completely in ten to twelve years if the rate of cutting continues at the present pace.

Taking a lead from CAP, and in line with widespread concern among the developing nations, many universities have introduced courses in environmental sciences in the past decade in Malaya. The University of Malaya in Kuala Lumpur has recently introduced a course in consumer law as part of its law degree, taught by one of CAP's founders in Penang.

But both CAP and IOCU — with its current president, Mr Anwar Fazal — argue that Western concepts of environmental consumer protection should be expanded to include concern for all aspects of industrial production, from factory working conditions to community health.

Even though Malaya has in recent years passed a variety of laws covering all areas, CAP claims that government authorities are frequently slow or reluctant to put these laws into effect. Officials that the magnitude of the task that faces them, and the continued pressure for economic growth, make it difficult to do any faster.

In a country where opportunities for political dissent remain limited — recently moved its Asian headquarters from Singapore to Malaysia — officials tread warily on the boundaries of legitimacy, aware that their requests for registration as a society could be questioned if their activities become overtly political.

But given the relative weakness of labour unions and official opposition parties, the consumer movement has become one of the few direct routes for attempting to influence government policies. "We create pressures within the bureaucracy" says Martin Khor Khok Peng, CAP's research director. "If we educate the public, the bureaucrats will have to listen."

## Conservation

### Bill of rights

The British government is hoping that its new Wildlife and Countryside Bill, introduced in the House of Lords last week, will be law by the end of next summer. Its passage through parliament, however, may not be easy. The bill has taken a long time to compile, preliminary consultation papers having aroused considerable opposition from conservation groups which do not feel that all inadequacies have been ironed out in the latest draft.

The chief effect of the bill is to bring British law in line with that of Europe, but Mr Tom King, minister for local government and environmental services, stresses that many of the new measures are badly needed anyway. The clauses in the bill on the protection of birds, methods of killing wild animals and the introduction of exotic species fulfil European requirements while those relating to nature conservation, the countryside and national parks are designed to improve wildlife management.

Mr King is especially pleased with the clauses relating to the management of areas designated as sites of special scientific interest (SSSIs). The conservation groups, however, say that these clauses are amongst the most worrying in the bill. Under them,

owners of some SSSIs will have a statutory obligation to inform the Nature Conservancy Council (NCC) of any planned operations which may affect the physical or biological features of the site and to wait for up to a year for the consent of NCC. Failure to notify would carry a penalty of up to two years imprisonment and a fine of £1,000 or both.

The conservationists will be seeking to amend these clauses to include all SSSIs, not just those singled out for special treatment, and to include some statutory obligation on the landowner to carry out the management recommendations of NCC. Under the bill, if agreement on management of a site is not reached within one year of notification, the landowner is free to carry out his original plan, although he may risk compulsory purchase by NCC.

On the whole, conservationists welcome clauses in the bill relating to the protection of wild birds, animals and plants, seeing them as a major improvement over existing legislation. The bill will tighten up the laws on the import and export of endangered species, methods of killing wild animals, keeping birds in captivity and selling them either dead or alive. Most of these amendments are in line with the European Community Directive on Wild Birds. The bill also seeks to protect "rare" creatures, such as the otter in Scotland, before they reach the endangered list.

A serious omission in these clauses, however, say the conservationists, is the lack of adequate provision for enforcement. They will be lobbying for the creation of a small investigation unit, probably under the aegis of the NCC, to give support and expert advice to customs officials and police who often miss infringements in the law because of unfamiliarity with wildlife.

Recent controversies about the main-

## Fallout from China

China's latest nuclear test on 16 October was "dirty" — according to the official Polish news agency PAP. The dust cloud had previously been monitored in Japan and New York, but the Polish agency reports of work from the Central Laboratory of Radiological Protection outside Warsaw is an example of the new policy of openness adopted by the Polish press. The laboratory has been working in the field since about 1973 with little publicity in Poland.

The Polish team, in the person of its leader, Dr Zbigniew Jaworowski, says that it has observed a significant amount of radioactivity at a height of 15 km. The Polish monitoring method is novel. A converted Mig-18 fighter flies horizontally through the dust cloud, opening a collecting duct at a predetermined altitude. The results suggested a fission-fusion-fission device, and this information was made available to the American group at the Environmental Protection Agency in Washington.

These aerial activities are not Dr Jaworowski's main interest, however. He is principally concerned with monitoring background levels of radioactivity — both natural and that produced by discharge of radioactivity into the atmosphere by "conventional" means — in Poland, largely from the combustion of coal. In September of this year Dr Jaworowski was appointed head of a United Nations commission on fallout, directly responsible to the General Assembly. His measurements of radioactivity levels in glaciers and icecaps throughout the world have met with some controversy, as he says that apart from a few black spots, the global build-up of radioactive fallout over the last century is far less than is claimed by the powerful "doomwatch lobby".

Vera Rich

English floodmeadows: threatened by ditch or protected by bill?

Photo: RSPB

tenance and safety of public footpaths are only partly dealt with in the bill. Although the rights of farmers to keep bulls in fields crossed by public footpaths will be restricted to some extent, beef bulls will be allowed if they are accompanied by cows. Ramblers will be no happier with that provision than with the transfer of general powers over footpaths from central to local government. Ramblers fear that local bias will mean that many paths are lost.

Although many conservationists agree that the bill improves on existing legislation, they consider it far from ideal. The opportunity to revise wildlife and conservation legislation comes up only about every five years so some hard fighting seems inevitable. The bill may have to take more blows than the government seems to have anticipated.

## Museum pieces

SIR — Halstead's progress report on the death of scholarship and the rise of Marxism in the Natural History Museum (*Nature* 20 November<sup>1</sup>) mixes too many different issues for a full reply. I will concentrate on his attack on scholarship in this institution. To Halstead, the symptom of decay is advocacy, in the public galleries, of cladistics, a method which he believes is being forced down the public throat by a Public Services Department which has overridden the views of scientists in the Museum.

Cladistics, as presented in the "Dinosaur" and "Fossil man" exhibits, may indeed seem oversimplified to some, or not fully thought through to others. But Halstead's alternative approach, as detailed in his comments on fossil man, seem to me far more grievously mistaken. In accusing us of lack of scholarship, he offers instead "the well attested sequence of human fossils representing samples of succeeding populations has . . . been taken as a classic example of the gradual evolution of a single gene pool. Certainly there is not any serious doubt about *Homo erectus* being directly ancestral to *Homo sapiens*". Confronted with these statements, one must either bow to Halstead's scholarship, or ask "attested" by whom? "been taken" by whom? "not any serious doubt" by whom? Halstead's answer might be, to quote the Museum handbook to the old exhibit on fossil man which was removed to make way for the dinosaurs, "the evolution of Man has come to be regarded as fact rather than hypothesis by all persons qualified to judge the evidence"<sup>2</sup>. In other words, we (scientists, experts, authorities) tell you it is so.

The radical departure in the exhibit reviled by Halstead is that the voice of authority is less strident. The visitor is encouraged to understand, and to take part in, the reasoning that underpins the story of human evolution; to become one of those "persons qualified to judge the evidence". And cladistics is the logical entry to that reasoning.

Amongst scientists in the Museum there are many different viewpoints on the value and generality of cladistic methods. Those viewpoints are a symptom of activity and debate. Halstead opts out of the debate, deferring instead to the authority of Mayr and Simpson, of books published 30 or 40 years ago, "and indeed of Charles Darwin himself". From his "reading of the literature of cladistics" Halstead concludes that cladists form the opposition "to the concept of gradualism and to the idea that the processes that can be observed at the present day, when extrapolated into the past, are sufficient to explain changes observed in the fossil record". This last idea, of extrapolating the present into the past as sufficient explanation, is usually attributed to Charles Lyell under the name uniformitarianism. Lyell's uniformitarian explanation of the changes observed in the fossil record was piecemeal extinction and creation<sup>3</sup>, an explanation invoking "qualitative leaps". Indeed, T.H. Huxley himself was unable fully to accept Darwin's gradualism, and preferred the saltationist camp. In short, Halstead's equation of cladistics and saltation is simply mistaken.

Recent advocates of saltation, and critics of extrapolation from population genetics to macroevolution, such as Gould<sup>4</sup> and Stanley<sup>5</sup>, are not cladists. Whether they are Marxists is another matter, in my view an irrelevant one.

More relevant is Halstead's confusion over the relation between cladistics, a method of systematics, and questions of process — modes of speciation or transformation of species. He sees a necessary connection between cladistics and one view of the evolutionary process, but as cladistic literature makes plain<sup>6-8</sup>, there is no such connection. Cladistics is not about evolution, but about the pattern of character distribution in organisms, or the recognition and characterization of groups. Halstead might direct his search for Marxist propaganda towards the Nuffield Biology texts and guides, for the teacher is urged "to develop a common vocabulary (and possibly notation) in biology and mathematics" by teaching the elements of systematics through Venn diagrams, which are logically synonymous with cladograms<sup>8</sup>. All that seems to lie behind Halstead's complaint is his failure to grasp the distinction between pattern (systematics) and process (explanation of the pattern)<sup>9</sup>. Hence his mistaken belief that he knows how evolution works, and that we are unwittingly committed to Marxist historicism.

SIR — In Dr Halstead's pleas for traditionalism in the Natural History Museum's exhibitions (*Nature* 20 November, p.208) he makes an assumption that lends much potential support to those whose policies he is so "fervently dedicated" to trying to discredit.

It is true that Marxists have attempted to equate the idea of punctuated equilibria (in its many guises) with the principles of dialectic, the head-on collision between changed environment and less well adapted organisms giving rise, by dialectic confrontation, to the new 'adapted' order, exactly as Marx envisaged the clash of the bourgeoisie and the proletariat, though Marx himself was somewhat vague in this area. Gradualism has been called on as evidence for other political persuasions. Politicians of all colours of the political spectrum have found things in Darwinism to support their political positions. As Shaw says of Darwin, "He had the luck to please everybody who had an axe to grind".

Unfortunately Dr Halstead is himself supporting the tenuous link between change in historical and present day human societies; between so-called "cultural

evolution" (which is a true Lamarckian system in any case) and the far slower and partially understood process of biological evolution, he is approving the idea that supposed historical events in evolution can be used as "scientific" evidence to predict and explain cultural evolution. Dr Halstead has only got under the surface of the argument, not to its core; he would surely be far better off questioning this primary assumption, rather than unintentionally lending support to biologically naive political thinkers. If he could do this, the problem he feels so strongly about would evaporate and he could escape. As it is, he is in great danger of being trapped by his position; his gradualist evidence is more tenuous than he implies, and since the recent Chicago conference it is probable that punctuated equilibria will indeed become a new orthodoxy. How will Dr Halstead free himself? With a "mighty leap" — a method some orthodox neo-Darwinians have been known to use?

The confirmation of his superficial attitude is given by his statement that, "Marxism will be able to call upon the scientific laws of history in its support". Dr Halstead clearly believes, as, of course, Marx did, that such "scientific laws of history" exist, but their emptiness has been elegantly demonstrated by Sir Karl Popper in *The Poverty of Historicism*, and *The Open Society and its Enemies*.

Having read Dr Halstead's views on Popper elsewhere I am not surprised at all by his confusion.

M. J. HUGHES-GAMES

Clifton,  
Bristol, UK

SIR — L.B. Halstead's letter (*Nature* 20 November, p.208) is misguided and, if his arguments were generally accepted, dangerous to the unfettered development of science. Whatever the scientific merits and demerits of the "cladist" theories behind the Natural History Museum's "Dinosaur" and "Fossil man" exhibits, it is most certainly wrong to attack them on the grounds that they might provide support for "a fundamentally Marxist view of the history of life". Indeed, it is ironic that Halstead should quote J.V. Stalin, for it was precisely his policy of encouraging the application of political criteria, rather than scientific ones, to assess scientific theories that ruined so much Soviet science for a generation.

It is really quite silly of Halstead to argue that because Marxist philosophers believe in revolutionary leaps (and, incidentally, so do several other, and quite different, philosophical and sociological schools of thought) then we ought to reject any scientific theory that explains changes in specific phenomena by way of "an abrupt leap from one state to another". How far is Halstead prepared to go with this "critique"? Should cosmologists now be called upon to reject the "big bang theory", topologists "catastrophe theory" or historians of science "paradigm breaks" because they might be construed as support for a law of Marxist dialectics?

## NEWS AND VIEWS

## Open debate

From M.G. Edmunds

THE simplest questions are often the hardest. It might be thought that 'What is most of the mass in the Universe?' should have been answered long ago, but a conclusive statement still eludes us. It is not too difficult to determine the radiation output of the galaxies, stars and interstellar material that we can actually see — with 'seeing' including radio, X-rays, infrared or ultraviolet, as well as visible light. From the amount of radiation we can infer the amount of radiating mass present. The resultant mass density of the Universe is comparatively modest, being only about one-fortieth of the 'closure' density required to exert sufficient gravitational pull to eventually halt the Hubble expansion and cause a re-collapse. The consequences of a closed or open Universe are rather remote on human timescales, but the problem exerts a strong philosophical attraction. Hence it is of considerable interest that there is growing evidence for a large amount of mass which does not radiate enough to have been seen, yet which might go a long way to making up the density required for closure.

The idea of 'missing mass' — mass that is present but not detected apart from its gravitational influence — is not a new one, and dates back to investigations of the dynamics of clusters of galaxies in the 1930s. In giant clusters, the rapid motions of the galaxies imply the existence of a gravitational potential well that is much deeper than can be explained by adding up the assumed masses of the visible galaxies. For many years there existed a feeling among astronomers that the 'missing mass' problem would eventually just go away when better observational data, or more appropriate theoretical treatment of that data, became available. But the problem has not gone away, and improved observations have all pointed to an upward revision of the mass density.

The most persuasive evidence for non-luminous matter comes from observations of the rotational velocities of spiral galaxies out to quite large distances from their centres (see, for example, Rubin, Ford & Thonnard *Ap. J.* **238**, 471; 1980). In many cases the velocities do not fall off with

distance from the nucleus but stay constant. A little elementary physics indicates this implies that the total mass inside a given radius increases linearly with radius. Yet the light output decreases exponentially with distance from the centre, so the matter in the outer parts must be many times less luminous per unit mass than the material in the inner parts. Since there is no evidence for a large amount of hidden material in the disk of our own Galaxy, it is likely that the dark mass in spirals has an extended, or 'halo', structure. Again from our own Galaxy, there is no evidence that the mass is in the form of faint stars.

It is obviously important to know how far the dark haloes extend, and how much they contribute to the total mass of a galaxy. Some evidence comes from the dynamics of small groups and binary pairs of galaxies, although the interpretation is difficult (see, for example, the excellent review of the whole question of galaxy masses by Faber & Gallagher *Ann. Rev. Astron. Astrophys.* **17**, 135; 1979; although considerably more galaxy masses have been published since this review, the general picture remains the same). Widely separated galaxies should sample the whole of each others' gravitational field, and such evidence as there is suggests the haloes could extend to 100 kpc, which is five or ten times the nominal visible extent of a typical galaxy. The dark material contributes as much, and probably several times as much, mass as the visible material.

If galaxies are considerably more massive than previously supposed, then this goes some way towards explaining the high dynamical mass implied for giant clusters of galaxies — but probably not all the way. There may still be several times more mass in the cluster than can be explained by adding up the (now heavier) individual galaxies. A new method of illustrating the presence of hidden material on an even larger size scale has been recently proposed (Davis, Tonry, Huchra & Latham *Ap. J. Lett.* **238**, L113; 1980),

*M.G. Edmunds is in the Department of Applied Mathematics and Astronomy, University College, Cardiff.*

which uses the motion of our local group of galaxies against the reference frame of the cosmic microwave background radiation. When this motion was first detected its direction was something of a surprise since it did not coincide with previous determination of the local group motion relative to other galaxies. Although the differences between the two motions are not fully understood, Davis *et al.* suggest that the component of motion towards the Virgo supercluster of galaxies, as determined in the microwave data, can be used to estimate the mean mass density of the Universe. They do this by considering the peculiar motions induced by perturbations of density (such as the Virgo superclustering) on an expanding Hubble flow. Their derived mean density is as high as four-tenths of the critical density required for closure. Thus the relative amount of mass which is hidden from view appears to increase with the linear size of the system — it is barely noticeable in the inner regions of galaxies, but becomes apparent at the outsides, it markedly influences groups and pairs, then dominates clusters and superclusters.

So what form is the dark mass in? The question is now a very important one since the dark mass is considerably greater than the visible mass. A population of low-mass objects can be imagined — interstellar material which condensed, became electron degenerate and is able to support itself without nuclear reaction. Such objects would have to be individually less than about one-twentieth of a solar mass. Large numbers of black holes or neutron stars are another possibility. But, apart from the difficulty of inventing a coherent picture to account for the formation of such objects without violating other constraints (notably limits to the amount of synthesis of heavy elements), there remains a fundamental problem if the missing mass is to be in conventional nucleon form. The dilemma comes from the effect of the extra mass on the nuclear reactions which synthesized helium and deuterium in the Big-Bang fireball at the beginning of the Hubble expansion. Putting the missing mass into nucleons

causes increased synthesis of helium and decreased synthesis of deuterium (see, for example, Yang, Schramm, Steigman & Rood *Ap.J.* **227**, 697; 1979). It might be possible to account for the observed deuterium in the Universe by production in other sites — perhaps supernova envelopes, although nobody has been able to think up an efficient enough mechanism. But overproduction of helium is a much more difficult problem, since it is not significantly destroyed (but rather added to) in normal stellar evolution and the observational limits on the maximum amount which could have been produced in the Big-Bang are now quite good.

The nuclear arguments would imply that the mass of nucleons in the Universe is not more than a tenth, and probably not more than a twentieth, of that required for closure. This corresponds to what we see in galaxies, although the error bars might just allow us to squeeze in the extra mass in galactic dark haloes as nucleons. The hidden mass in clusters, or that implied by Davis *et al.*'s Virgo supercluster argument would cause too much primordial helium production and far too little deuterium. A possible solution lies in the existence of a sea of massive neutrinos, left over from the Big Bang. The case for such a sea has been eloquently argued by D.N. Schramm and G. Steigman in this year's Gravity Research Foundation first-prize essay (to be published in *General Relativity and Gravitation*. See also Sybailis, Yang & Schramm *Nature* **288**, 143; 1980). They argue, on the basis of consideration of the clustering properties of massive neutrinos (see Tremaine & Gunn *Phys. Rev. Lett.* **42**,

407; 1979) that the most likely neutrino mass would be  $3\text{eV} \leq m \leq 10\text{eV}$ . The extra mass of these neutrinos would allow the missing mass in galaxy clusters to be explained, but problems would still remain if Davis *et al.*'s (albeit indirect, and somewhat uncertain) mass density is correct, or if closure is desired. The difficulty is that putting more and more neutrinos into the Universe will eventually cause degeneracy of the neutrino sea, which would again affect primordial element production. At one-tenth closure density, this does not appear to be a problem, but at much higher densities a more massive neutrino would be required, and it is not clear that such a neutrino would cluster in the right way to provide the increase of missing mass fraction with linear scale of the system considered. Astrophysicists will be eagerly awaiting experimental evidence of neutrino masses (see *Nature* **286**, 755; 1980), and further investigation of the clustering of neutrinos would seem important.

Whether the majority of mass in the Universe really is a sea of neutrinos, or whether it is conventional nucleon matter, remains to be decided. But the existence of considerable dark matter has been demonstrated. It is not so long ago that a headline appeared in a North American newspaper reporting "Caltech astronomers declare Universe open". Although the evidence still remains in favour of openness, one cannot help wondering if (in apparent obedience to current financial stringencies) the Universe may not be all that far from closing again. □

expanded the structural details along more speculative lines to propose evolutionary trees based on the variations between polypeptide subunits in ATPases.

The argument still rages in mitochondrial bioenergetics as to how many protons are translocated at each energy conservation site in the electron transport chain, S. Papa (Bari) favouring two whilst other groups favour three or four. Unfortunately, experimental measurements show little prospect of resolving this problem. Since extensive research has failed to implicate any quinone in the transfer of electrons from cytochrome *b* to cytochrome *a*, there is speculation about an alternative mechanism of proton translocation, possibly involving multiple  $\text{H}^+/\text{e}^-$  ratios. In contrast, research using chromatophores has provided strong evidence for the involvement of a specific quinone (Z) between cytochromes *b* and *c*, and the requirement for a quinone pool for ATP synthesis.

New evidence for the role of quinones in electron gating was discussed by A. R. Crofts (Urbana). In both chloroplasts and photosynthetic bacteria there is evidence that a quinone reduces cytochrome *b* only on even flashes of light, that is, only after the formation of  $\text{QH}_2$ , which would fit with the original ideas of a Q cycle. As Z has been identified as different from  $\text{Q}_2$  however, this must be rejected and an alternative mechanism of quinone oxidation invoked, although the proponents of a linear chain model have not explained how it copes with two electrons simultaneously. The concept of gating raises many problems, not least being the interpretation of the results of repetitive flash experiments used to measure rates of electron transport in photosynthetic systems. In mitochondria, although much evidence now points away from a classical Q cycle, no real alternative was put forward.

A system for examining an alternative non-Mitchellian mechanism of proton translocation is the bacteriorhodopsin proton pump from halobacteria. However, it was evident from the discussion that this apparently simple system is resistant to experimental analysis and is still a long way from providing a useful model. One recent, interesting development is the discovery that there is also a light-driven sodium pump in these organisms, possibly using a second retinal protein (J.K. Lanyi, Max-Planck-Institute, Munich).

Calcium transport was covered extensively but no new theories were presented and the sessions were devoted to discussing the alternative mechanisms for calcium release from mitochondria which are sodium insensitive. There is still no consensus as to which of three different methods is the more probable, polyunsaturated fatty acid induced-efflux, oxidation of mitochondrial pyridine nucleotides or an indirect inorganic phosphate-induced pathway.

## Bioenergetics in Europe

from Judith Armitage

THE First European Bioenergetics Conference, held in July in Italy, showed that, with the general acceptance of the chemiosmotic concept of energy transduction, interest has moved from the gross theory to the finer, molecular and genetic details.

The problem of elucidating the functional, *in vivo* structure of the membrane-bound energy-transducing proteins using isolated systems and physical techniques was one of the basic themes of the conference. This problem was well illustrated by the many discussions on the possible structure of cytochrome oxidase, and its relation to function. R. Capaldi (Oregon) using X-ray diffraction and image reconstruction on the isolated enzyme described the possible functional

arrangement of the seven polypeptides across the membrane. Although local interactions *in vivo* and the precise role of each subunit is still unknown, the experimental data and *in vitro* structural studies were used by M. Wikström (Helsinki) to speculate on the possible mechanism of proton translocation by the protein and its relationship to the conservation of the membrane potential, emphasizing the need to consider both molecular and electrical topography within the protein.

Using very similar *in vitro* techniques on the crystallized  $\text{F}_1\text{-ATPase}$  M. Amzel and coworkers (Johns Hopkins) proposed a model for the structure of  $\text{F}_1\text{-ATPase}$  as a functional dimer, rather than the previous triple/single structure. There are, however, at least two arrangements of the subunits which would yield a dimer and fit *in vivo* experimental data. Some speakers

Judith Armitage is in the Department of Botany and Microbiology, University College London.

### 100 years ago

The recently-presented budget of Prussia shows that, despite the financial straits of the kingdom, no considerations of economy are allowed to hamper the growth of its scientific and educational system. First on the list come the nine universities with an allotment of 7,050,000 marks (352,500/). Berlin receives the lion's share, 1,378,348 marks, an increase of about 37,000 marks on its last annual subvention. Bonn and Königsberg each have 740,000 marks, Breslau 600,000, Kiel 404,000, Marburg and Halle each 430,000, Göttingen 201,000, and Greifswald 136,000. Of the above-mentioned sum about 1,306,000 marks are appropriated for extraordinary expenses in connection with the construction of university

buildings, and of this amount Berlin absorbs over one-half, viz., 766,000 marks. The other chief items in the Budget of Public Instruction are: Gymnasias and Realschulen, 5,000,000 marks; primary schools, 14,500,000; orphanages, schools for the blind, deaf and dumb, &c., 300,000; technical schools, and for the general furtherance of science and art, 3,000,000 marks.

The number of pupils of Lycées and Colleges in the French Republic is 87,000 (46,500 for Lycées and 40,500 for Colleges). Last year it was only 84,700. These establishments may be considered as analogous to the English grammar-schools.

Mr. Mundella has been speaking on education again, repeating essentially the old story, that our country must lose in the race unless, as in other countries, education in science is made an imperative part of elementary education. We have many natural and traditional advantages over other countries, but all these must in the long run succumb to scientific training.

From *Nature* 22, 2 December, 106 & 115, 1880.

Historically, Heuser had been interested in the use of rapid freezing to study exocytosis in neurotransmission. To trap exocytosis during membrane fusion and allow examination by freeze fracture techniques, Heuser and his colleagues devised an apparatus for the very rapid freezing of nerve-muscle preparations in liquid helium a few milliseconds after electrical stimulation (*J. Cell Biol.* 81, 275 1979). From here it was a small step to apply this rapid freezing, platinum replica technique to other preparations such as fibroblast cytoskeletons.

What advantages does this approach have? Heuser suggests that it avoids the use of chemical fixation of whole cells, a procedure which, by definition, is denaturing and which may, therefore, be a source of artefacts. Heuser and Kirschner compare the images of triton cytoskeletons that were prepared before or after fixation with glutaraldehyde. The filaments in cytoskeletons prepared from fixed cells appeared with variable thickness, partially agglutinated and covered with irregular deposits while those prepared from unfixed cells were more discrete entities, had more regular and consistent dimensions, and were frequently recognizable, for example, as actin filaments or intermediate filaments. The general appearance of the cytoskeletons prepared from fixed cells resembled the 'microtrabeculae' described by Wolosowick and Porter (*Am. J. Anat.* 147, 303; 1976; *J. Cell Biol.* 82, 114; 1979), who have described this structural matrix in whole cells fixed with glutaraldehyde and viewed by high voltage electron microscopy. The similarity of the cytoskeletal preparations from fixed cells has led Heuser and Kirschner not to question the existence of the microtrabecular lattice but to suggest that its appearance, with irregular dimensions and anastomosing filaments may result from the use of glutaraldehyde and the consequent cross-linking of filaments and

## A new view inside cells

from Keith Burridge

LIKE so many areas of science, electron microscopy does not advance smoothly but in quantal jumps which are often the result of the introduction of a new technique. The use, for example, of glutaraldehyde as a fixative by Sabatini and his colleagues in 1963 made possible the visualization of the cytoplasmic filaments that are so much studied today.

Perhaps the most recent and exciting advance in electron microscopy, gracing the pages of the *Journal of Cell Biology* with dramatic images, has come from J. Heuser and his colleagues (*J. Cell Biol.* 84, 560; 1980; Heuser & Kirschner *J. Cell Biol.* 86, 212, 1980). Heuser's approach differs

greatly from the conventional method of examining thin sections of cells that have been fixed (with agents such as glutaraldehyde and osmium tetroxide), dehydrated, embedded, sectioned and stained with heavy metals. Instead, Heuser and his colleagues have rapidly frozen either whole cells or cytoskeletal preparations (cells extracted with nonionic detergents), opened the cells by freeze fracture, removed the volatile components by freeze drying, and rotary shadowed the remaining structures with platinum. These platinum replicas are then examined by transmission electron microscopy (TEM) (Figures 1 and 2).

**Figure 1** Two views of cytoskeletal elements. *a* is a tangle of filaments from the perikaryal region of a freshly plated cell which would stain diffusely for actin by light-microscope immunocytochemistry. The filaments display a 5.5nm repeat or graininess that appears to be characteristic of actin filaments as revealed by this technique. *b* shows filaments from a similar area but after decoration with the S1 fragment of myosin. (From J. Heuser and M. W. Kirschner *J. Cell Biol.* 86, 226, 1980.)

**Figure 2** High magnification of a coated pit area on the cytoplasmic face of the plasma membrane of a fibroblast. Bar =  $\mu\text{m}$ . (From J. Heuser *J. Cell Biol.* 84, 564; 1980.)

adsorption of cytoplasmic proteins to them during fixation.

Although this may be true, it is important to realize that when Heuser and Kirschner make a cytoskeleton without fixation, many proteins are extracted and these most probably include a number that bind to or cross-link the filaments such as the actin-binding proteins (filamin,  $\alpha$ -actinin, myosin, etc.). Whereas the cellular images obtained by Wolosowick and Porter may contain fixation artefacts that contribute to the microtrabecular appearance, equally the images of Heuser and Kirschner may be oversimplified by the extraction of many of the bridging elements. Perhaps a more accurate image lies somewhere between these two.

A second advantage of Heuser's approach is that the image comes from the platinum replica. With conventional thin sections and most whole mounts viewed by TEM the final image is due to the selective binding or deposition of heavy metals, such as osmium, uranium and lead. Since the chemistry of this selective staining has not been fully worked out, there is a degree of uncertainty in the interpretation of the final image. In particular, if a cytoplasmic structure is not stained, it will not be seen. On the other hand, the replica technique should mirror the surface of the cytoplasm, cytoskeleton, or intact cell very closely. However, herein lies a problem and a limitation of the technique. When unfixed cells are rapidly frozen and then fractured so as to reveal the cytoplasm, it is difficult to reveal any structure other than a complex granularity. To obtain unimpeded views of cytoplasmic structures such as the various filaments, this granularity must be extracted or diluted. Hence cytoskeletons are excellent material for this approach but whole cells present problems. These may be partially overcome by swelling the cell briefly in distilled water or by fixing a cell first and then washing it in distilled water. Presumably, both procedures eliminate the salts and other unetchable components, but the one method reintroduces the problem of chemical fixatives whereas the other exposes cells to an osmotic shock. Although these approaches do not appear suitable for examining the cytoplasm of whole cells, they have generated some very interesting views of the cytoplasmic face of the plasma membrane (*J. Cell Biol.* **84**, 560, 1980). Indeed, the ability to view the cytoplasmic face of the membrane may be one of the most valuable contributions of this whole technique.

Part of the appeal of the images achieved by Heuser's technique comes from the depth of the three-dimensional view (similar in appearance to scanning electron micrographs). Viewing only the surface of structures avoids superimposing their upper and lower faces which occurs with thin objects in conventional thin sections.

Examining the platinum replicas of microtubules after rapid freezing and fracture, it is possible to discern the tubulin subunits in a 3-start helix, something that has only previously been seen after optically filtering electron micrographs of negatively stained preparations. Similarly, the geometry of coated pits and vesicles is particularly clear in Heuser's pictures since the upper and lower faces of these structures are not superimposed (Figure 2).

The resolution of the technique as used by Heuser is about 2nm and easily picks up, for example, the 4nm repeat of tubulin monomers in microtubules. The resolution is sufficient to distinguish the different filament types by their surface

substructure, although the resolution is less than with negative stain. When actin is decorated with the S1 subfragment of myosin, the image of an actin filament is transformed into a double-stranded rope-like structure. Like the underlying actin filament, this reveals a 5.5nm axial periodicity (Figure 1). Heuser and Kirschner also demonstrate that the technique has sufficient resolution to visualize IgG molecules directly without additional electron-dense labels. This application is particularly exciting and may permit the ultrastructural localization of accessory proteins which previously have been seen in the filament systems only by immunofluorescence.

## Pathways of endocytosis

from Michael Geisow

ENDOCYTOSIS is an elegant biological solution to two related needs of living cells — the need to retrieve material bound to the plasma membrane and the need to recover the membrane itself. But what components of the membrane enter the cell and what happens to them?

Exogenous ligands — nutrients or effectors — bound by receptors at the plasma membrane collect within differentiated regions known as coated pits. The cytoplasmic coat is thought to be composed of clathrin and, provided that the temperature is above 10°C, bound ligands are cleared from the coated pits, to lodge [ultimately] in cytoplasmic structures containing hydrolytic enzymes.

The composition of coated pits is of some interest. It has been presumed that coated pits are enriched in the appropriate receptors which enter the cells together with bound ligand. Naturally, this assumes the continued fidelity of the receptor part of the labelled ligand complex. What other components of the plasma membrane also disappear into the pit?

In the fibroblastic cell at least two intrinsic membrane polypeptides appear to stay clear of coated pits. Ferritin markers linked via specific antibodies to these two membrane proteins (the  $\theta$  and H63 antigens) were found by Mark Bretscher and colleagues to be excluded from pits<sup>1</sup>. In contrast, ferritin and other labels conjugated to low density lipoprotein<sup>2</sup> and epidermal growth factor<sup>3</sup> clustered selectively in these regions. The coated pit may also control some selection of its own lipid components as suggested by the apparent exclusion of cholesterol<sup>4</sup>.

Since all components of the plasma membrane of fibroblasts can be renewed the observations on the  $\theta$  and H63 antigens means that such proteins must be taken up by other routes — otherwise the plasma membrane would act as a dead end for

redundant copies of the proteins. Perhaps the alternative route in this case is via uncoated membrane invaginations seen to sequester ferritin-labelled HLA antigens<sup>5</sup>. Coated pits observed in the same cells were free of marker.

The majority of proteins or peptides which enter the cell by endocytosis appear to be deposited in secondary lysosomes or multivesicular bodies (essentially the same thing). Do the associated receptors coincidentally suffer the same fate? At least one well-studied receptor<sup>6</sup> — for epidermal growth factor — does appear to be destroyed together with its bound hormone<sup>6</sup>. For a number of other receptors, there is evidence of efficient recycling. Results obtained from studies of the hepatocyte galactose receptor and low density lipoprotein receptors in fibroblasts are exemplified by recent observations<sup>7</sup> of the mannose/N-acetyl glucosamine receptor (macrophages).

Only a small fraction of the total cellular pool of sugar receptors are present on the macrophage surface at any time. However, if the accessible copies are destroyed enzymically at low temperature they can be rapidly and repeatedly replaced upon warming the cells, even in the absence of protein synthesis. Similar treatment of cells at 37°C quickly destroys the entire receptor stockpile suggesting that receptor turnover is fast and continues even in the absence of specific ligand. The galactose receptor in hepatocytes has a long intracellular half-life, of several days — an observation obtained after challenge with saturating amounts of specific ligand<sup>8</sup>.

For these receptors it is necessary to envisage recycling and to postulate that receptor and ligand part company somewhere between coated pit and secondary lysosome. Two recent articles describing the route of ligands entering cells via coated pits provide a new structural context for biochemical approaches to this problem.

In hepatic cells, Wall *et al.*<sup>9</sup> have traced

Keith BurrIDGE is in the Cold Spring Harbour Laboratory, New York.

Michael Geisow is in the National Institute for Medical Research, Mill Hill, London.

the route of ligands expressing galactose residues. Numerous coated pits were seen in the absorptive membranes of cells before exposure to ligand. Coated vesicles close to the membrane were almost invariably shown to be pits lying with their principal axes roughly parallel to the plasma membrane as recently observed by others<sup>1,12</sup>. Ligand first seen in these pits was found one and a half minutes later inside irregular structures (vesicles and tubules) lacking coats. After five minutes ligand appeared in the Golgi-lysosome region of the cell inside a heterogeneous population of uncoated structures. The appearance of ligand in association with lysosomal enzymes was first apparent at fifteen and complete at sixty minutes. Another recent report<sup>10</sup> suggests the delay in fusion of pinocytic vesicles with lysosomes has a half-time of only seven minutes. Nevertheless, there does appear to be some agreement that ligand entering cells via coated pits takes longer to complete this standard journey than by other uptake routes<sup>11</sup>.

Willingham and Pastan<sup>12</sup> present findings with strikingly similar features. In addition to electron microscopy, a system of image-intensified fluorescence microscopy permitted continuous observation of their ligand —  $\alpha_2$ -macroglobulin — as it was taken up by fibroblasts. They found no evidence of coated transport structures other than the initial coated pit. Instead the ligand transferred from pits to uncoated, irregular vesicles apparently like those described by Wall *et al.*<sup>9</sup> with no clear transitional stage. The cytoplasmic structures were highly mobile and did not combine with anticlathrin antibodies; nor did they show any affinity for antibodies to the major microtubule or microfilament proteins. One more point of similarity between the Wall and the Willingham articles concerns timing. Label was in uncoated structures after five minutes, in the Golgi-lysosome region in fifteen minutes and in lysosomes after thirty minutes. To distinguish the uncoated vesicles arising as a result of endocytosis through coated pits from other pinocytic vesicles, Willingham and Pastan have coined the term 'receptosome'.

Concerning the new nomenclature, one might comment that the name would be even more appropriate if one could be sure that the receptors were still there. In the structures described by Willingham, the reaction product of their marker — conjugated peroxidase — did seem to be associated with the limiting membrane. However, the higher resolution marker employed by Wall *et al.* — conjugated ferritin — appeared throughout the lumen of the transporting vesicles at this stage. They speculate that dissociation of receptor and ligand might have already occurred.

Each of these recent articles emphasise the role of the clathrin-coated pit as a

# PATHWAYS OF ENDOCYTOSIS IN CELLS

structure specialising in receptor transfer across the plasma membrane. Strong evidence for a similar role has been reported for coated regions in endoplasmic reticulum membranes<sup>13</sup>. On the other hand direct evidence for coated vesicles as putative transport structures is as rare as coated pits are common. Recent reports either state or imply that the existence of coated vesicles, is extremely transient. Instead, the transport structures themselves appear to be smooth-membraned vesicles. It's worth noting that the isolation of coated vesicles containing ligand<sup>13</sup> does not prove their independent existence as cytoplasmic entities, since homogenisation of plasma or Golgi membrane containing coated pits is very likely to produce closed vesicles when the membranes rupture.

The irregular appearance of the uncoated transport structures<sup>9,11</sup> may imply intense membrane fusion activity — secondary lysosomes and Golgi condensing vacuoles are two examples of this. The 'receptosomes' of Willingham and Pastan might well act as a short limbo for incoming receptor-ligand bearing vesicles and, in the case of receptors which recycle, for

departure of vesicles bearing receptor alone. The delay in lysosomal sequestration of label entering cells by receptor-mediated endocytosis accords with the requirement for prior dissociation of ligand and receptor. However, entry via coated pits does not appear to be mandatory for a delay in lysosomal fusion, since HLA antigen complexes which are endocytosed in uncoated structures<sup>14</sup> are also slow to appear in multi-vesicular bodies. The key to fusion or complete absence of fusion (as in the case of epithelial cells mediating transport across the cell layer) may lie in the proteins expressed upon the surface of the (uncoated?) transport structures.

I now anticipate the characterisation of 'Charonosomes' named after Charon who was able to return in his ferry after his passenger had crossed the point of no return into the underworld to face dissolution or immortality. But even more I await the direct, covalent labelling of a surface receptor. Surely, only a technique of this kind will enable the current models of receptor recycling and receptor-mediated endocytosis to achieve the elegance of the biological processes they seek to explain.

## The slow process of succession

from Peter D. Moore

THERE are certain areas of ecology which are made more difficult to investigate by the current tendency to limit research grants to three years. Take the long-term study of plant competition between bracken (*Pteridium aquilinum*) and heather (*Calluna vulgaris*) on the Brecklands of East Anglia. If Alex Watt (*J. Ecol.* 43, 490; 1955) had been restricted to a three-year study period, plant ecology would be much the poorer. Then there is the study of successional processes, which may take several hundred years to reach completion. The subject is of considerable interest to both pure and applied ecologists but short-term studies have considerable weaknesses.

Some brief research projects concerning succession have been undertaken, such as that of Tramer (*Ecology* 56, 905; 1975) who observed abandoned agricultural plots over a three-year period. But it is difficult to derive general statements concerning the nature of the process from such a restricted view. Many researchers have tried to solve this problem by observing the extant stages in successions which have been proceeding for different lengths of time. Classical studies such as those of Crocker and Major (*J. Ecol.* 43, 427; 1955) on a glacial retreat recolonization and Olson (*Bot. Gaz.* 119, 125; 1958) on the sand dunes of the Great Lakes region are of this type. Similar studies have used abandoned agricultural land of known history, such as those of Bazzaz (*Ecology* 56, 485; 1975) and Nicholson and Monk (*Ecology* 55, 1075; 1974). This approach suffers from the disadvantage that one must assume that study sites are alike in all but the developmental time factor. Naturally, this is hardly ever the case.

Ideally, one would like to take a single location and study the changes in plant and animal populations over many decades, or even centuries. In Britain we are fortunate in that one such experiment has been in progress for over a century, and some of the resulting data has now been analysed by Silvertown (*J. appl. Ecol.* 17, 491; 1980).

This is the Park Grass Experiment at Rothamsted Experimental Station, which was begun in 1856 and which was originally intended to study the effects of various fertilizer regimes on grassland composition and productivity. The subdivision and replication of treatment plots was improved in 1964, but the data analysed by Silvertown covers only the period up to this revision.

From 1862, samples were cropped from the plots, were separated into species, dried and weighed. Plots which had received regular applications of ammonium sulphate were of lower pH and lower diversity (Shannon function), and all plots showed a negative relationship between overall biomass and diversity (and species richness).

The succession at Rothamsted has reached an equilibrium condition, under the constraints of harvesting imposed upon it. It is essentially a plagioclimax in the Tansley sense. Yet the variation of the equilibrium point in relation to nutrient capital and therefore biomass is of considerable interest for the theory of succession.

It adds considerable weight to the ideas of Green (*Biol. Conserv.* 4, 378; 1972) who regarded the successional process in chalk grassland to be an accretion of nutrients in the biomass and litter, resulting in increased dominance and consequently reduced diversity among the plants. The results also fit well into the Grime model (*Nature* 242, 344; 1973) if one regards increased fertilization as 'reduced stress', but the term over-simplifies the complexity of the system by reducing it to one dimension.

One of the particularly interesting features of the development of short turf into tall turf (increasing biomass) in grassland succession is that its influence upon invertebrate diversity is the reverse of that found in plants. As plant diversity falls, invertebrate diversity increases. This is considered by Morris (In *The Scientific Management of Plant and Animal Communities for Conservation*, ed. E. Duffey and A.S. Watt, Blackwell, Oxford, 527; 1971) to be a consequence of the increased opportunities for herbivorous grazers in the structurally and

microclimatically more complex environment offered by tall grassland plants. This, of course, will increase diversity at higher trophic levels also.

An Australian experiment has recently confirmed this relationship by monitoring the invertebrate faunas associated with different stock density of sheep. Hutchinson and King (*J. appl. Ecol.* 17, 369; 1980) sampled sites over a three year period which were grazed at densities of 10 sheep ha<sup>-1</sup>, 20 ha<sup>-1</sup> and 30 ha<sup>-1</sup>. Apart from Scarabaeid beetle larvae and Oligochaeta, which showed greatest mean abundance (no. m<sup>-2</sup>) and biomass in intermediate grazing levels, other groups showed a reduction in biomass and density as the grazing pressure increased. Here again, grazing pressure can be considered as a controlling influence upon habitat structure.

But what of vertebrates? Small mammals, like invertebrates, are more abundant in taller, undisturbed turf (Duffey, *J. Anim. Ecol.* 31, 571; 1962), but birds, particularly those which use grassland for feeding, seem to prefer short turf. In Sweden, Larsson (*Oikos* 20, 136; 1969) has shown a considerable decrease in the numbers and diversity of birds frequenting the grassland areas around some Swedish lakes, following the removal of cattle grazing, and the consequent increase in vegetation cover.

This change in avifaunal diversity and density with the successional development from short to long turf has some interesting implications for applied ecology. A survey by Brough and Bridgman (*J. appl. Ecol.* 17, 243; 1980) of thirteen airfields in Britain has shown very considerable differences in the density of feeding birds in short and long turf. The total counts over a two year period showed that three times as many birds overall used the short turf sites (which was defined as being a grass height of 5-10cm) when compared to long turf sites (grass height 15-20cm). In the case of gulls, the numbers feeding in long grass were only one fifth of those in short turf habitats. Their distaste for long turf may be associated with a greater difficulty in feeding upon soil invertebrates, coupled with a lack of visibility which might allow the approach of predators.

There thus seems to be a strong case for allowing the grassland succession on airfields to proceed beyond the short-turf stage and thus reduce the risk of bird strikes for aircraft. As Brough and Bridgman point out, however, there is one snag. The increased small mammal populations of the long grass may attract avian predators, such as kestrels and short-eared owls. But the data which they present suggests that these species are unlikely to reach seriously high population levels.

It would be pleasant to think that such a practical application of the study of what are essentially successional processes might encourage further and longer term studies.

Peter D. Moore is in the Department of Plant Sciences, University of London King's College.

# Actin assembly

from Sarah E. Hitchcock-DeGregori

A survey of the literature shows that the study of actin filament assembly is positively booming although it is one of the older areas in the contractile protein field.

Understanding of the polymerization of many protein polymers grew out of biophysical studies begun in the 1960s on the mechanism of actin polymerization<sup>1</sup>. The conversion of monomeric actin (G-actin) into filamentous actin (F-actin) has been viewed as a two-step condensation-polymerization process: condensation of a few actin monomers to form nuclei (the rate limiting step), followed by addition of monomers to form actin filaments (elongation). At steady-state, the F-actin is in equilibrium with a critical concentration of G-actin. Wegner<sup>2</sup> has proposed that actin elongates by a 'head-to-tail' mechanism, with a net addition of monomers to one end of the filament and a net depolymerization at the other end. While experimental work has supported the Wegner model, recent work suggests that the mechanism of actin assembly and disassembly may be more complex in detail<sup>3-5</sup>. The 'polymerizing' end of the filament has been shown to be the end that appears barbed in filaments decorated with myosin HMM or S<sub>1</sub><sup>6,7</sup>. It is also the end that is attached to the Z-line in muscle, to dense bodies and to microvilli.

The model seemed particularly suitable to those working on muscle as in rabbit and frog skeletal muscle actin is in 1  $\mu$  long thin filaments, and once assembled with tropomyosin and troponin to this miraculously constant length, it seems to stay there until it needs to be turned over for new protein. Although many questions remained unanswered, other aspects of muscle contraction, such as regulation and myosin kinetics, received more attention in the 1970's.

This situation has now changed with the new emphasis on non-muscle motility. Bray and Thomas<sup>8</sup> showed that a substantial amount of actin from cells is in a non-filamentous form. In addition, there have been numerous reports of changes in the state of actin which correlate with changes in cell shape and function.

It is now believed that the state of actin assembly is specifically regulated at a number of points, including (at a minimum) nucleation, addition of monomers at the net polymerizing end, loss of monomers at the net depolymerizing end (or other sites of depolymerization), and association of filaments to form bundles and networks. Nature has aided studies of these problems by supplying ready-made poisons, the cytochalasins and phalloidin, which interfere with one or more of these processes.

Sarah E. Hitchcock-DeGregori is in the Department of Biological Sciences, Carnegie-Mellon University, Pittsburgh.

First, the problem of nucleation. Although ionic conditions in the cell are highly favourable for polymerization of actin, much of it is non-filamentous. A protein called profilin that prevents the polymerization of actin has been isolated from a variety of sources<sup>9,14</sup>. Profilin combines with G-actin and inhibits the formation of nuclei. The dissociation of profilin from actin is promoted by agents that are known to form sites of attachment for actin filaments in cells. For example,  $\alpha$ -actinin is found in the Z-line and at other sites of filament attachment such as dense bodies in smooth muscle and adhesion plaques of stress fibers in cultured cells. Long suspected to be a promoter of actin polymerization,  $\alpha$ -actinin has now been shown to dissociate profilin from actin, thereby allowing polymerization<sup>16</sup>. Similar results are found with spectrin-actin complex from erythrocyte membranes and with nuclei of purified actin<sup>12,17,18</sup>. Once nucleation has taken place, elongation ensues, resulting in filament growth.

Assuming nucleating sites exist at all times in cells, an obligatory site of regulation is the elongation step. Cytochalasins and proteins with properties resembling cytochalasin are believed to regulate elongation. Research has focussed on the effect of cytochalasins on actin polymerization<sup>19</sup>. Cytochalasin binds to F-actin and spectrin-actin complex and inhibits polymerization, presumably by competing with the G-actin for the nucleating site. There is general agreement that, in terms of Wegner's head-to-tail model of elongation, cytochalasin inhibits polymerization by preventing addition of monomers to the preferred polymerization end, the barbed end of decorated actin filaments<sup>20,27</sup>. This results in net depolymerization and shortening of existing actin filaments. In addition, some investigators believe cytochalasin may also alter or fragment filaments<sup>28,30</sup>. It is probable that in the final analysis the mechanism of cytochalasin will be complex.

Recently, there have been reports of proteins with cytochalasin-like activities: from platelets<sup>31</sup> and *Acanthamoeba*<sup>32</sup>. The platelet factor competes with cytochalasin B for spectrin-actin complexes, inhibits polymerization of G-actin on to these complexes or on to actin nuclei, and when added to preformed actin filaments causes a slow loss of viscosity. The *Acanthamoeba* factor appears both to promote nucleation and to inhibit the rate of elongation. There is electron microscopic evidence that in the presence of this protein, actin monomers are added at the pointed end but not at the barbed end of the filament. When the factor is added to filamentous actin, some depolymerization is observed. Isenberg *et al.* have interpreted these results to suggest

that their factor, which they call capping protein, may promote nucleation by stabilizing actin dimers and then inhibiting elongation by allowing growth only in the 'slow' or pointed direction. Capping protein (see this issue of *Nature*, p 455) and the platelet protein<sup>33</sup>, like cytochalasin B, reduce the low shear viscosity believed to result from interactions between ends and sides of filaments and between filaments and other actin binding proteins<sup>27,28,34</sup> and gelation factors<sup>35,37</sup>. A factor with similar properties to capping protein has been isolated from conventional muscle actin preparations<sup>38</sup>. These proteins may have a role in regulating the consistency of the cytoplasm.

From these reports it seems highly likely that capping or cytochalasin-like proteins may regulate the elongation of actin filaments on existing nucleating sites. This leaves us the problem of depolymerization of actin. Change in cell shape involves, in some cases, rapid dissolution of filamentous structures. From *in vitro* studies, it appears unlikely that factors blocking the net polymerizing end of actin (if this is the correct interpretation) or nucleation (profilin) could cause rapid depolymerization, since the ionic conditions of the cytoplasm are highly favourable for polymerization. Rather, it seems likely that there will be factors that actively depolymerize actin. DNase I depolymerizes actin rapidly, apparently by acting directly on the filament<sup>3,39</sup>. Other factors that depolymerize actin in seconds or minutes *in vitro* have been isolated from plasma and serum<sup>40,42</sup> and the presence of depolymerizing factors in cells has been reported<sup>42,43</sup>. The detailed mode of action of these factors is the next problem that will have to be elucidated.

## Where do cosmic rays come from?

from a Correspondent

ABOUT once a second a single atomic nucleus carrying on its own at last 10 Joules of energy from Space hits an air nucleus in the Earth's atmosphere. It thereby initiates an enormous shower of secondary particles which builds up to an extensive air shower (EAS) of  $10^{10}$  particles by the time it reaches sea-level. Such a primary cosmic ray particle has been accelerated somewhere in the Universe through the equivalent of a voltage difference of  $6 \times 10^{19}$  volts. How and where this acceleration takes place remain among the major unsolved questions of high energy astrophysics.

The origin of cosmic ray particles has been a subject of controversy for more than 50 years and has resulted in something of an East-West divide amongst astrophysicists. On the one side V. L. Ginzburg (P. N. Lebedev Institute of Physics, Academy of Science of the USSR, Moscow) and others have argued consistently that these cosmic ray nuclei originate mainly in our own Galaxy. On the other side, British theoretical astronomers, such as G. R. Burbidge (University of California), have maintained that the sources must be extragalactic. Whichever viewpoint is held, however, there is general agreement that supernovae explosions play a significant part in cosmic ray particle acceleration.

Most cosmic rays, of course, have energies far less than the highest energy particles; the spectrum at the Earth peaks at energies of  $10^9$  eV per nucleus and falls rapidly to energies greater than  $10^{20}$  eV per nucleus ( $1 \text{ eV} = 1.6 \times 10^{-19}$  Joules). At the highest energies ( $>10^{18}$  eV per nucleus) astrophysicists have so far failed to produce a satisfactory model for the acceleration mechanism. Almost by a process of elimination, however, the net seems to be closing in on possible source regions. Briefly the case is as follows. The ultra-high energy particles cannot originate and remain captured in the Galactic disc because the Galactic magnetic field is not strong or extensive enough to contain the particles. For a Galactic origin it is generally thought that strong anisotropy in the particle arrival directions should exist — presumably from the centre of the Galaxy. Again, the particles cannot come

from the deep depths of space. They could not travel that far without colliding with the Universal  $2.7^\circ \text{ K}$  microwave background photons and undergoing strong absorption through pion production at energies greater than  $10^{19}$  eV per nucleus. The experimental evidence shows that rather than a cut-off in the cosmic ray energy spectrum occurring at  $10^{19}$  eV, it is just at this point that a flattening of the spectrum appears to occur. So where does that leave us?

The latest East-West confrontation took place recently in the beautiful old Russian capital of Leningrad where the VIIth European Cosmic Ray Symposium was held from September 15th-19th. Here A. W. Wolfendale (University of Durham) suggested that the problem could be resolved by a model in which those ultra-high energy particles reaching the Earth come predominantly from the nearby local supercluster of galaxies in Virgo. The actual sources would be active galaxies within the cluster of 2,500 galaxies. Wolfendale and his colleagues have developed their model to explain the available experimental data and it predicts an obvious anisotropy in the particles arrival direction at the Earth. Such an anisotropy in the general direction of Virgo is indeed observed for the highest energy particles detected by the Haverah Park EAS Detector Array in Yorkshire (*16th Int. Cosmic Ray Conf. Kyoto* **13**, 130; 1979).

At Leningrad J. Lloyd-Evans (University of Leeds) presented the latest data on the anisotropy analysis from the Haverah Park Group. These indeed confirm a sharp and significant change in the phase of preferred arrival direction from low Galactic latitudes to high positive latitudes as the primary energy increases above  $10^{19}$  eV in EAS detected at Haverah Park. This change occurs sharply at  $10^{19}$  eV per nucleus, just where the flattening in the energy spectrum is observed. So the Wolfendale model fits in well with the latest experimental data.

However, the 'extragalactic' Western scientists were not allowed to have it all their own way in Leningrad. D. D. Krasilnikov (Inst. of Cosmophysical Research and Astronomy, Yakutsk, USSR), presented a paper entitled

'Intensity Anisotropy of Highest Energy Cosmic Rays, its Energy Dependence'. In this the author considers the distribution on the celestial sphere of all the 313 cosmic ray particles with energies above  $10^{19}$  eV detected by the four large EAS detector arrays in England, Australia, US and the USSR. Krasilnikov too demonstrates that the anisotropy increases and changes phase as the primary energy increases. In particular, he selects out for special treatment the particles with energy/  $3 \times 10^{19}$  eV/nucleus. He splits the data in half in four different ways: (a) those coming from below and those above the Galactic equatorial belt of  $\pm 30^\circ$  latitude; (b) those coming from inside and those outside the Galactic equatorial belt of  $\pm 30^\circ$  from the Galactic centre; (c) those coming from opposite hemispheres pointing towards and away from the Galactic centre; and (d) those coming from opposite hemispheres pointing towards and away from the centre of the Virgo cluster. Taking the ratios of the intensities from the two groups in each of the four cases, Krasilnikov finds that only in case (c) does the intensity ratio ( $= 0.43 \pm 0.14$ ) differ significantly from unity. Thus he claims the measured anisotropy is associated with Galactic co-ordinates. The author therefore concludes that these results point to a Galactic source for the particles and infer a mass composition of heavy or middle mass nuclei and a modulation of their propagation directions by Galactic disc and halo magnetic fields. He argues that although supernovae can only directly accelerate the particles up to  $\sim 10^{17}$  eV per nucleus, further acceleration can be achieved by the magnetic fields of the Galaxy, both disc and halo, over time scales of  $10^7$  to  $10^8$  years.

Significantly, Krasilnikov needs heavy primary nuclei to support his theory. Unfortunately, as yet, there is little experimental guide as to the primary mass composition at these energies. What there is suggests that protons are still abundantly present as at lower energies. The East v West battle is thus still alive. We must now await the next round, to take place at the 17th IUPAP Conference in Paris next July.

The Leningrad symposium was, not unexpectedly, dominated by the Russians, since they combined the biannual European Symposium with an annual national cosmic ray meeting. The great magnitude of the Russian effort showed up forcefully in the special workshop session devoted to cosmogenic nuclides — that is the study of individual nuclear isotope concentration in meteorites. The analysis and interpretation of such data is now reaching a very high degree of sophistication.

### ERRATUM

In the News and Views article "Lessons from a peptidergic neurone" by B. T. Pickering (13 November, **288**, 117; 1980) the molecular weights quoted were incorrectly altered by the insertion of 'K' and should instead be read in Daltons.

*Pictures taken from Voyager 1 between 3 September and 13 October 1980 at a resolution of ~1,000 km/lp reveal new data on Saturn rings.*

THE Voyager 1 spacecraft was launched on 5 September 1977 and successfully flew past Jupiter on 5 March 1979, assuming a trajectory to encounter Saturn on 12 November 1980. By mid-summer of 1980, at a range from Saturn of ~1 AU ( $1.5 \times 10^8$  km), the resolution of the Voyager Imaging System<sup>1</sup> had equalled that achieved in excellent seeing conditions with ground-based telescopes. Since then, pictures of the planet and its rings have revealed steadily increasing detail. We present here a preliminary discussion of imaging data for the rings at a resolution of about 1,000 kilometres per line pair (km/lp), corresponding to approximately 0.1 arcs as seen from Earth.

During the Voyager approach the spacecraft has viewed the planet from above (north of) the ecliptic plane, showing the rings open at an angle of ~9°. When seen from Earth at a similar opening angle, the surface brightness of the rings (illuminated by the Sun at about the same angle) is comparable to that of the planet. However, the rings as seen by Voyager are much darker, being illuminated at a low solar angle; the inclination to the Sun increased from zero on 3 March 1980 to 3.4° on 1 October.

The images we are using for the present analysis were obtained during the Voyager 1 Observatory Phase between 3 September and 13 October 1980. During that period the range to Saturn decreased from  $92 \times 10^6$  to  $40 \times 10^6$  km, and the resolution improved from 1,700 to 800 km/lp. The details of the ring are best shown in 3-s exposures with the clear filter (~300–650-nm bandpass). The photometric calibration of the Voyager cameras has been discussed in detail elsewhere<sup>2</sup>. We follow the traditional nomenclature for the rings of Saturn given by Alexander<sup>3</sup> and Cook *et al.*<sup>4</sup>, reserving the problem of naming recently observed structures within the rings until all of these features have been adequately defined.

### Appearance of the rings

As the spacecraft has approached Saturn, finer radial structure in the rings has become apparent. At a range of ~1 AU (~3,000 km/lp), the Encke Division in the A ring was first clearly visible. At ~0.5 AU, the existence of a separate maximum within the Cassini Division was apparent, and two prominent minima in the C ring became visible. By the time the resolution was 1,000 km/lp, considerable fine structure between the major divisions was apparent, and the first evidence of azimuthal structure appeared in the central parts of the B ring. Figure 1 illustrates the ring as seen at this level of resolution.

Table 1 lists the radial features of the rings that can be seen at a resolution of 1,000 km/lp. The terms maximum and minimum refer to features, possibly unresolved, in the radial brightness distribution. At higher resolution it may be possible to deter-

mine if these relative minima are clear regions with widths below our 1,000-km resolution limit, or are simply zones of lower particle density. Similarly, the features we now describe as relative maxima may reveal internal structure (for example, zones of lower brightness) at higher resolution.

The most dramatic discovery from images at 1,000-km/lp resolution has been extensive azimuthal structure within the B ring, at distances of ~104,000–116,000 km from the centre of Saturn. These non-axisymmetric features take the form of lanes, which are seen near the ring ansae, approximately radial to the planet, and 5–10% darker than surrounding areas. The time resolution during Observatory Phase (one observation each 2h) is insufficient to follow the evolution of any particular marking, so we do not know the lifetimes of these features, except that some persist for at least 3 h. A more detailed discussion of the non-axisymmetric features will be given elsewhere.

### Individual features

The centre of the Encke Division is at a distance of 133,400 km from the centre of Saturn ( $2.21 R_s$ , where  $R_s = 60,330$  km<sup>5</sup>). It is barely resolved in the Voyager images, indicating a width of 1,000–2,000 km. The position agrees well with that measured in transmission by Gehrels *et al.*<sup>6</sup> whereas the width seems somewhat greater than Gehrels' measurement (876 km).

The Cassini Division has a width of about 4,000 km and is centred at 118,900 km ( $1.97 R_s$ ). It shows a nearly symmetrical brightness profile, as illustrated in Fig. 2. In the centre is a narrow ring, clearly separated from the A and B rings on either side. At current resolution this ring appears to be ~2,000-km wide. This ring also was seen by Pioneer, where it showed as a dark core in the bright Cassini Division; however, in diffuse transmission, as seen by Pioneer 11, it was ambiguous whether this feature corresponded to a local maximum or minimum in particle density. We now see that it is a maximum.

The most prominent features in the B ring, at this resolution, aspect and epoch, are three bright bands in the outer half of the ring, at distances of 102,300 km, 108,000 km and 116,300 km (see Fig. 2). Just outwards of the innermost bright feature is a minimum whose amplitude is time variable, which forms the inner boundary of the non-axisymmetric dark features that extend outwards almost as far as the outer edge of the B ring.

Inwards from the bright band (at 102,300 km) is a darker lane, followed by a fairly smooth decline in brightness to the edge of the B ring at 92,200 km. There is no indication of the deep minimum and prominent maximum near the inner edge reported by Dollfus<sup>7</sup>.

There are two prominent minima within the C ring, one at

**Fig. 1** *a*, *b* and *c* are three separate enhancements of a single Voyager 1 clear exposure (34032.33), taken on 13 October 1980 at a range of  $40.5 \times 10^6$  km (resolution 750 km/lp). *a* is enhanced to show the relative brightness of the major ring features: the C ring, B ring, Cassini Division (and material therein), A ring and Encke Division. *b* has been enhanced to show radial structure within the A and B rings. In *c*, the darker C ring has been enhanced. *d* is an image which was taken on 4 October 1980 from a distance of  $52 \times 10^6$  km (resolution 960 km/lp) and illustrates the non-axisymmetric structure that has been discovered in the outer part of ring B.

86,700 km and one at 77,300 km. Because neither is fully resolved at 1,000-km resolution, we do not know how dark these gaps are. The inner minimum (77,300 km) has not been previously reported whereas the outer minimum corresponds closely to a feature observed by the Pioneer 11 IR investigation<sup>8</sup> and apparently accounts for a feature seen in a Pioneer photograph of the ring shadow on the disk of Saturn. Gehrels *et al.*<sup>6</sup> erroneously assumed that this minimum was at the boundary between the B and C rings and identified it with the brightness maximum in diffusely transmitted light at the outer edge of the C ring, at 90,000 km. We now see that there is no prominent minimum between these two rings, and the minimum observed by Voyager is  $\sim 5,000$  km inwards of the B-C boundary.

The dimensions we obtain at a Voyager resolution of 1,000 km for the boundaries of the A, B, and C rings agree well with those obtained from ground-based observations<sup>4,9</sup> and from Pioneer 11 (ref. 6).

### Ring structure and satellite resonances

The radial structure in the rings has long been believed to result from the effects of gravitationally induced perturbations in ring

**Fig. 2** The brightness profile of the rings at 750-km/lp resolution is shown here, using the same image as Fig. 1*a-c*. On the left is Saturn's terminator. The dotted line in the Encke Division (133,500 km) indicates the location of a reseau mark in the original data; here the profile is taken from an adjacent trace (that is, one just removed from the image's semi-major axis) through the data. The small peak at 140,000 km is the F ring.

particle orbits resulting from resonances with the inner satellites, particularly Mimas (see, for example, ref. 10). The satellites S10 and S11 (refs 11, 12), both orbiting near the edge of the ring at  $1.51 \times 10^5$  km, provide potentially stronger perturbations than does Mimas. Other satellites may also have an influence on radial structure, particularly in view of the complex ring structure shown in the Voyager images. Because the difference in orbital longitude varies slowly for the two co-orbital satellites, S10 and S11 (ref. 13), ring structure may also have time-variable components.

Table 1 lists the assigned resonances for the various features in the rings. Table 2 lists all members of two types of resonance which fall within the rings. The satellites S10, S11, Mimas, Titan, Hyperion and Iapetus are the only ones which generate resonances of these two types within the rings. The resonances are characterized by multipliers of the mean orbital longitudes of the satellite,  $j'$ , and the particle in the ring,  $j$ . Resonances of Type I appear to the zeroth power in the orbital eccentricity of the satellite and involve  $j' - j = 1$ . Resonances of Type II, which are generally weaker, appear to the first power in the orbital eccentricity of the satellite and involve  $j' - j = 2$ . Note that resonances of Type I at  $j' = 1, j = 0$  involve an equality of the rate of advance of the line of apsides of a ring particle and of the mean motion of the satellite. The motions of the apsides are those induced by Saturn's oblateness.

Table 1 Ring features

| Feature  | Position*<br>( $\times 10^3$ km) | Position*<br>( $R_s$ ) | Resolved | Possible<br>resonance†                               |
|----------|----------------------------------|------------------------|----------|--|
| Saturn   | 60.33                            | 1.00                   | —        | —  |

| S10, S11   | II   | 14   | 12  | 2.267                 | Not separable from next                     |
|            | I    | 7    | 6   | 2.267                 | Outer edge, A                               |

Tables 1 and 2 show that as the density of matter in ring C increases outward, the divisions due to S10 and S11 disappear; this happens first for resonances of Type II, then for those of Type I. Those of Type I reappear outside the Cassini Division and may form the outer edge of ring A. For Mimas there is good evidence only for resonances of Type I. The Type I apsidal resonance from Iapetus may contribute to structure within the Cassini Division. Hyperion's small size casts doubt on the assignment listed.

It is clear from Tables 1 and 2 that the classical satellite resonances do not explain most of the fine structure seen in the rings. Some of the structure may be generated by the presence of small, as yet undiscovered satellites within the rings, for example, at the edges of major divisions. These satellites may produce additional maxima and minima through their orbital resonances; they may also serve as sources for some of the ring material. The presence of the spoke-like azimuthal structures in the B ring reminds us that other dynamical processes may also be important in producing observed features.

### Preliminary ring photometry

The ring brightness is of great interest, as it contains implications as to the constituent particle albedos and phase functions. Several previous studies<sup>14,15</sup> have been conducted to determine these parameters. We have made preliminary model calculations of ring brightness using a doubling-adding radiative transfer code<sup>16</sup> for the geometry of these observations. Although the data reduction is as yet preliminary, certain overall conclusions may be drawn.

Due to the low Sun angle ( $\sim 3^\circ$ ), the dependence of observed brightness on layer optical depth is small. We find that the constituent particles of the A and B rings are characterized by a greater degree of diffuse backscattering ability than previously

suspected. In fact, particles behaving like Lambert spheres provide quite a good fit to the observed A- and B-ring brightness.

However, the C ring has noticeably different properties. For an optical depth  $\sim 0.1$  (refs 15, 17), the C ring would be nearly as bright as the A and B rings at the present epoch, if the constituent particles were identical. However, Voyager observations show it to be less than half of the A and B brightness. Fuller phase-angle coverage, obtained subsequently in the mission, will be required for a distinction to be made between albedo and phase-function effects. However, the unambiguous implication is that the C-ring particles are different, either darker or more highly forward scattering than the A- and B-ring particles. This qualitative conclusion is consistent with the conclusions of recent analyses of Pioneer Saturn data<sup>15,18</sup>. This observation argues very strongly for a different particle population in the C

ring as compared with the main rings. More data and analysis will refine these preliminary conclusions.

The figures and much of the data reduction for this article were provided by the Image Processing Laboratory at the Jet Propulsion Laboratory. We particularly thank G. W. Garneau and L. R. Doyle for assistance. G. E. Hunt is supported by the SRC. This report presents the results of one phase of research carried out at JPL under NASA contract NAS7-100.

*Note added in proof:* Subsequent Voyager observations have shown the azimuthal features which appear dark in back-scattered light reverse contrast and appear bright against the background B ring in forward-scattered illumination. This behaviour indicates that these features result from concentrations of small particles (a few micrometres) and not from variations in the B-ring particle density.

## Planform of mantle convection beneath the Pacific Ocean

*The correlation between variations of the bathymetry and of the geoid in the Pacific Ocean suggests that both are the surface expression of mantle convection. The planform of the convection which is required to generate the observed anomalies does not consist of rolls but is three dimensional, with rising and sinking jets elongated in the direction of motion of the Pacific plate relative to the frame of reference defined by the hot spots. The spacing between the maxima and minima of the geoid is between 1,500 and 2,000 km and hence favours a model of mantle convection with multiple scales of circulation.*

ALTHOUGH most geophysicists agree that plate motions are maintained by mantle convection, there is little agreement about the geometry of the motion which converts heat into work. One of the principal difficulties is that the motion of the plates themselves provides a few restrictions on the form of the flow, because their motion can be described by rigid body rotations. Runcorn<sup>1</sup> recognized that long-wavelength gravity anomalies should be directly related to the fluid motion, and McKenzie *et al.*<sup>2</sup> showed that upper surface of the convecting region with constant viscosity was elevated, producing a positive gravity anomaly, over the rising region of the flow. The influence of the elastic forces within the plate on the magnitude and sign of the anomalies of gravity and bathymetry above a convecting region<sup>3,4</sup> is small if their wavelength is  $> 500$  km and the elastic thickness of the plates is  $\leq 30$  km (ref. 5). The wavelengths are expected to be at least twice the depth of the convecting region, or  $> 1,400$  km, if the convection is confined to the upper mantle. The amplitudes of the gravity and bathymetry anomalies obtained from the numerical calculations are about 20 mGal and 500 m respectively. Hence the anomalies should be easily observed, correlated with each other, and be little affected by the elastic behaviour of the plates. Two difficulties must be overcome before geophysical observations can be used to examine the convective planform. The first involves corrections to the observed bathymetry to remove the effects of lithospheric

age, determined from the magnetic anomalies, and of sediment loading. Both of these can now be calculated with reasonable accuracy, and the depth obtained after these corrections has been applied is known as the residual depth. Only that part of the residual depth which is not produced by variations in crustal thickness and whose wavelength is longer than  $\sim 500$  km is dynamically maintained by the convection. The other difficulty concerns the gravity field. Surface observations contain large amplitude short wavelength anomalies, and long wavelength errors are produced by drift of the instrument and calibration errors. For these reasons the long wavelength gravity anomalies can only be reliably obtained from surface ship observations in areas where there is dense coverage.

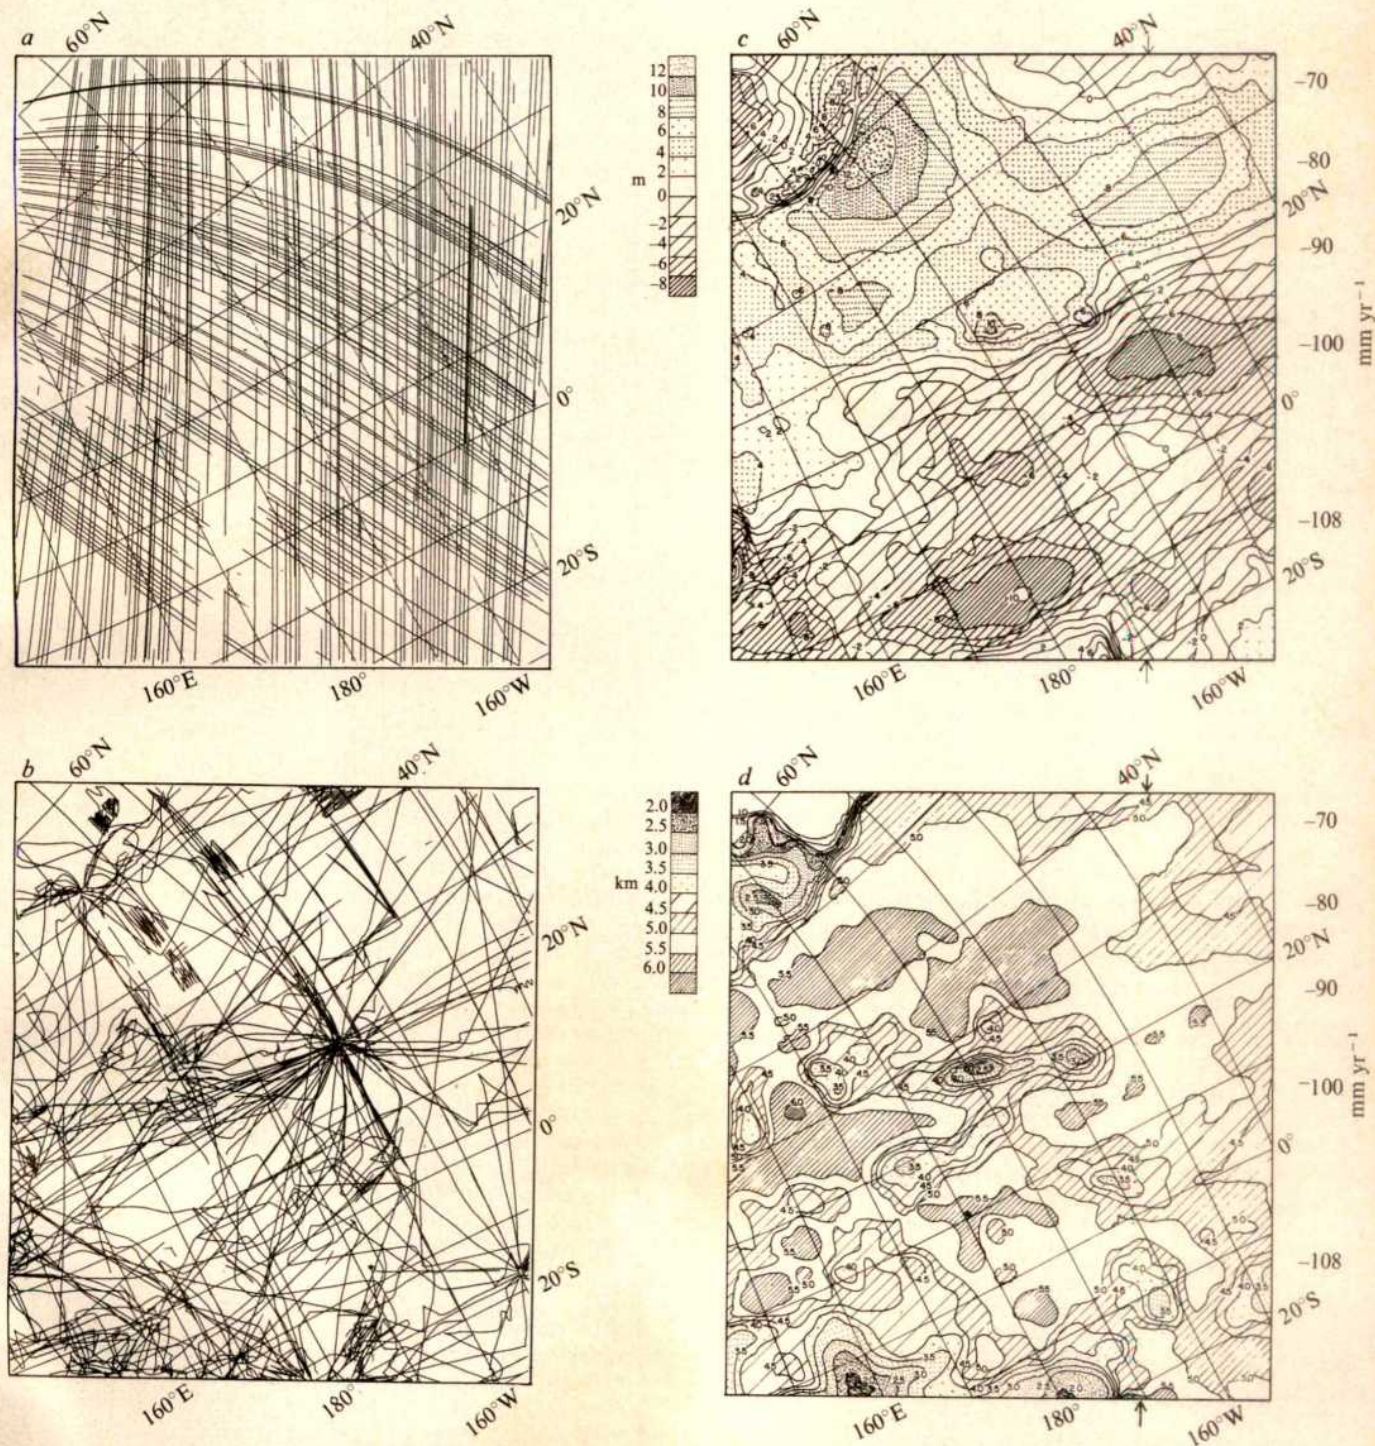

### Historical techniques

The first attempt to use these arguments to investigate mantle convection<sup>6</sup> used the depth of the ridge axis and a satellite-derived gravity field. The procedure avoided the use of depth corrections, as the age of the ridge axis is the same everywhere and the sediment cover is very thin. Although the correlation between gravity and residual depth was clear in the North Atlantic, where it agreed with the numerical calculations, it was much less convincing in the other oceans. This behaviour was probably produced by errors in the satellite gravity field, whose

higher harmonics were poorly determined. Extensive two-dimensional investigations of gravity and residual depth anomalies in the North Atlantic<sup>4</sup> and the Pacific around Hawaii<sup>7</sup> using surface gravity observations showed good agreement with the numerical models but neither covered a large enough area to demonstrate the convective planform. Cochran and Talwani<sup>8</sup> considered a larger region but failed to find a global relationship between gravity and residual depth similar to that found in the smaller regions<sup>4,7</sup>. Their lack of success was probably due to the poor sampling of the long-wavelength part of the gravity field due to the wide spacing of the ship tracks. Figure 3 shows that the amplitude of the gravity anomalies corresponding to 10 m variations in geoid height is only  $\sim 20$  mGal. Such gravity

anomalies will be difficult to detect in the presence of short wavelength anomalies of hundreds of mGal produced by seamounts, and measurement errors of at least 10 mGal. Menard and Dorman<sup>9</sup> attempted to use the bathymetry alone to examine the convective planform. Because long-wavelength variations in bathymetry may be isostatically compensated, and hence be unrelated to mantle convection, it is not obvious what constraints a study of the bathymetry alone imposes on the form of the circulation (see Fig. 2). An attempt<sup>10</sup> to obtain a gravity field over the Pacific from satellite orbits and surface gravity seems to have produced spurious anomalies, due to lack of sufficient surface observations and an instability caused by downward continuation<sup>11</sup>.

**Fig. 1** Satellite altimeter (a) and ship (b) tracks used to obtain contour maps of geoid (c) and bathymetry (d) in the North and Central Pacific. The projection is an oblique mercator projection with axis  $61.7^\circ\text{N}$ ,  $-82.8^\circ\text{E}$ . Contour intervals are 2 m for (c) and 0.5 km for (d). The grid spacing in both cases is 100 km at the equator of the projection, and the gaussian half width for interpolation is 110 km for (c), 150 km for (d). The velocities shown on the right of (c) are those of the Pacific plate, moving from right to left, relative to the hot spot frame<sup>15</sup>, and is  $108 \text{ mm yr}^{-1}$  at the equator of the projection.

A detailed analysis of the gravity field and surface deformation above different types of convection<sup>12</sup> showed that their ratio depends little on the form of the heating, the Rayleigh number, or the boundary conditions. Hence little further progress could be made until more accurate estimates of gravity anomalies between wavelengths of 500 km and 5,000 km became available over large areas of the oceans. GEOS 3 has now provided such estimates by direct determination of the geoid.

### GEOS 3 measurements

The GEOS 3 satellite contains a radar altimeter which measures the distance from the satellite to the sea surface. If the orbit of the satellite and oceanographic corrections are known the geoid can be obtained directly. In practice, the precision of the altimeter is between 0.5 and 1 m, and analysis of the cross-over errors between different tracks shows errors of  $\sim 10$  m (ref. 13) due to orbit errors. The orbit errors can be reduced to about 0.6 m by adjusting the orbits to minimize the cross-over errors<sup>13</sup>. We used these adjusted heights. Oceanographic corrections consist of tides and both time-dependent and steady-state variations produced by currents. These corrections are poorly known, but are probably  $< 1$  m in most parts of the ocean and were therefore ignored. The heights  $h_i$  corrected for bias and trend<sup>13</sup>, at points described by radial unit vectors  $\mathbf{a}_i$  were then filtered with a gaussian filter to give a smoothed height  $H_i$  at position  $\mathbf{b}_i$ ,

$$H_i = \sum_j h_j \omega_j / \sum_j \omega_j, \quad \mathbf{b}_i = \sum_j \mathbf{a}_j \omega_j / \sum_j \omega_j$$

$$\omega_j = \exp(-d_j^2/\sigma^2) \quad (1)$$

where  $d_j$  is the distance between a chosen point on the profile and  $\mathbf{a}_j$ , and  $\sigma$  is the half width of the gaussian filter, chosen to be 100 km. In addition a weight  $W_i$  was obtained from the ratio of the rectangular approximation to the integral of the filter to the true integral

$$W_i = S \sum_j \omega_j / \sigma \sqrt{\pi}$$

where  $S$  is the spacing between successive points on the profile. If  $W_i < 0.3$  the point was rejected. This processing reduced the number of data points while leaving unchanged longer wavelength features of the geoid. Because the geoid is dominated by long wavelength anomalies ( $\lambda > 5,000$  km) and we are principally interested in those of intermediate wavelength, we subtracted the GEM7 geoid<sup>14</sup> up to and including  $l = m = 10$ . GEM7 was used because this geoid was determined from satellite orbits alone, and because the coefficients of degree and order  $< 10$  agree excellently with those of more recent determinations. The points  $\mathbf{b}_i$  were projected onto a plane to give a position  $\mathbf{x}_i$ , and  $H_i$  then interpolated onto a square mesh using equation (1) with  $\sigma = 110$  km,  $d_i$  being the distance between a mesh point and  $\mathbf{x}_i$  in the plane of the projection, provided  $d_i < 4\sigma$ . Otherwise  $\omega_i$  was set to zero. Finally the grid values were machine contoured. The bathymetry obtained from digitized profiles of more than 400 cruises in the Pacific Ocean treated similarly, except for the interpolation onto a square mesh where  $\sigma = 150$  km was used.

### Results

Figure 1 shows contour maps of the geoid and bathymetry, together with the satellite and ship tracks used. The area was chosen because it is large and well studied. Except in the upper right-hand corner of Fig. 1 sediment thicknesses are thin and uniform, and hence sediment loading corrections, which were not made, will produce little change in Fig. 1d. The depths in Fig. 1 have also not been corrected for subsidence as the lithosphere cools. Such corrections are also only important in the upper right-hand corner of Fig. 1, because the remainder of the area studied is underlain by lithosphere older than 60 Myr. The projection is an oblique mercator projection with the pole of relative motion between the Pacific plate and the hot spot frame

as an axis<sup>15</sup>, and the mesh spacing in Fig. 1c,  $d$  is 100 km on the equator of the projection. The region shown in Fig. 1 covers most of the North and Central Pacific. An accurate short wavelength anomaly produced by the Aleutian Island Arc is clearly visible at the top left of Fig. 1c, the anomaly on the left-hand edge is produced by the Mariana Island Arc, and those along the bottom by the Solomon and Tonga arcs. The geoid contours show the existence of elliptical maxima and minima whose amplitude is about 8 m and whose separation is between 1,500 and 2,000 km. One of the largest of these anomalies is associated with the Hawaiian Swell and has already been mapped using ship profiles<sup>5</sup>. The anomalies in Fig. 1c are too large and their separation is too great to be supported by the elastic part of the lithosphere, and therefore they must be dynamically maintained by mantle convection. Figure 1d shows that many of the geoid anomalies in Fig. 1c are associated with bathymetric anomalies. Figure 2 shows two profiles obtained from the values of the geoid and the bathymetry on the mesh points and plotted against distance in the oblique mercator projection to show the correlation more clearly. These two profiles are in the eastern part of the Pacific, where the geoid anomalies are large. The shoal region at the northern end of the profile is produced by the young lithosphere near the Gorda and Juan da Fuca ridge crests. This bathymetric anomaly does not correlate with the geoid and will be removed by the age corrections which have not yet been applied. Such corrections will not remove depth variations which are maintained by variations in crustal thickness, produced by vulcanism either on ridge axes or within plate interiors. Two such features, the Line Islands ridge and the Manihiki Plateau, are crossed by the profiles in Fig. 2 and both were produced by ridge axis vulcanism. Neither the crustal thickness nor the density of such ridges is well known, and therefore corrections are hard to apply. Towards the trench systems in the west the geoid is flatter than in the east, and several small anomalies of 2 and 4 m are associated with some of the large aseismic plateaus, such as the Shatsky and Hess Rises. Ridge axis vulcanism, which builds aseismic ridges at or above sea level on thin lithosphere, gives rise to anomalies of this magnitude, and there are many such features in the western Pacific<sup>16</sup>.

The geoid anomalies in Fig. 1c are mostly elliptical, with the long axes of the ellipses approximately parallel to the  $x$  axis of the plot. As the projection is an oblique mercator projection whose axis is the pole of relative motion between the Pacific plate and hot spot frame, the rigid motion of the Pacific plate in Fig. 1c corresponds to a translation in the  $x$  direction. The relative velocity in this projection is  $v_0 \operatorname{sech} y$ , where  $v_0$  is the equatorial velocity and  $y$  is the vertical coordinate of the mercator projection, and is shown on the right of Fig. 1c. The ellipticity suggests that the convective pattern is elongated in the direction of motion. The contours provide evidence that the elongation increases with increasing velocity.

### Discussion

The above observations provide various constraints on models of mantle convection. Perhaps the most important is that the geoid strongly suggests the existence of mantle convection whose horizontal scale is considerably smaller than that of the plates themselves, and that the elongation of the anomalies in one direction results from the shearing of the circulation by plate motions. Such a model has previously been proposed on theoretical grounds<sup>3,17</sup>; where it was argued that the spacing between the rising and sinking regions should be similar to the depth of the convecting layer, and that the planform of the flow would probably consist of rolls aligned with their axes in the direction of motion, at least beneath rapidly moving plates such as the Pacific. This conclusion was qualified by Skilbeck and McKenzie<sup>18</sup> who used an approximate method to examine the stability of a model suggested by Richter and McKenzie<sup>19</sup>, which possessed a low viscosity zone beneath the plates which decoupled the horizontal movement of the plates from that of the mantle below. The calculations suggested that even the Pacific

**Fig. 2** Profiles of the geoid (*a*) and bathymetry (*b*) between the arrows on Fig. 1c, d. The horizontal axis shows the *y* coordinate in the oblique mercator projection, and the scale applies at *y* = 0.

was unlikely to be moving sufficiently fast to stabilize rolls, and that the small scale flow would probably be three dimensional. An alternative explanation is suggested by the experiments of Richter and Parsons<sup>17</sup> on the evolution of sheared convection. As the geometry of the Hawaiian Ridge requires the motion of the Pacific plate in the hot spot frame to have changed ~40 Myr ago, the present direction of motion may not have existed for long enough to have established rolls. It is obviously of interest to extend the observations of Richter and Parsons<sup>17</sup> to slower shearing rates.

Figure 3a, b and c shows the geoid, bathymetry and gravity produced by the convective flow in Fig. 3d, e. The depth of the convective layer is 700 km, the Rayleigh number is  $1.4 \times 10^6$ , and the flux is fixed at  $58.5 \text{ mW m}^{-2}$  on both boundaries (see refs 2 and 20 for details). Both horizontal and vertical scales are the same as those in Fig. 2 at the equator of the projection. Both the horizontal scale and the amplitude of the bathymetry and geoid in Fig. 3 are similar to those in the Pacific. Superimposed on the cellular circulation is a time-dependent flow driven by hot and cold blobs detaching from the boundaries. This flow produces obvious bathymetric and gravity anomalies, but the wavelength is too small to produce more than 1 m anomalies in the geoid. Similar numerical experiments with the more realistic boundary condition of a plate superimposed on top of the convecting region also show that the spacing is often considerably greater than the layer depth (G. Houseman, personal communication). Hence the geometry suggested by Fig. 1 is to be expected, and is not evidence for whole mantle convection.

An unexpected feature of the geometry of the geoid anomalies is that they are larger in the east where the plate is young than they are in the west where it is old. This distribution suggests that they are not the result of instabilities beneath the cooling plate, and hence are not related to the flow postulated by Parsons and McKenzie<sup>21</sup> to account for the observed relation between depth and age. The anomalies are better explained by instabilities of a lower hot boundary layer, perhaps at the base of the upper mantle. Near the trenches, where cold material is returned to the base of the convecting layer, the lower boundary layer is stable. As this material moves towards the east it is warmed by heat conducting into the upper mantle from the lower mantle, and becomes unstable. The same behaviour is clearly seen in the right-hand cell in Fig. 3d. The geoid anomalies are the surface expression of these instabilities.

Transfer of heat to the base of old lithosphere could still be produced by small cold blobs detaching from its base, similar to those on the right of Fig. 3d, because the geoid anomalies they would produce would be similar in magnitude to the noise (Fig. 3a). Such blobs would, however, produce obvious anomalies in the gravity field (Fig. 3c).

Some of the existing models of the return flow on a spherical Earth<sup>22-24</sup> show that the return flow is approximately antiparallel to the plate motion, and therefore can account for the elongation of the geoid anomalies in Fig. 1. All these models, however, neglect the thermal buoyancy forces in the interior of

the convecting region. As such forces are dominant within large aspect ratio convective cells, such as that on the right in Fig. 3, the direction of flow obtained from the model calculations may not agree well with that in the mantle.

## Conclusions

The observations discussed above have little relevance to whether the convective circulation involved in plate movements is confined to the upper mantle or extends throughout the whole mantle. If the whole mantle is convecting its Rayleigh number must be  $10^9$ – $10^{10}$  and the flow must be principally driven by internal heating. In these conditions the horizontal scale is

**Fig. 3** Profiles of the geoid (*a*), bathymetry (*b*) and gravity (*c*) above a convecting fluid where the planform of the convection consists of two-dimensional rolls normal to the plane of the page. In all three cases the surface deformation obtained by the method outlined in ref. 12 has been convolved with the response of an elastic plate 30 km thick<sup>3</sup>. The horizontal scales are the same as those in Fig. 2 at the equator of the projection, and the vertical scales are the same. The temperature (*d*) contoured at 100°C intervals and the stream function (*e*) at 0.1 intervals are for a Rayleigh number of  $1.4 \times 10^6$  with both upper and lower boundaries stress free and deformable. All the heat is supplied from below and the heat flux, not the temperature, is fixed on both boundaries (see ref. 20 for details).

controlled by the thickness of the boundary layer, and may be much smaller than the depth of the layer itself. In contrast, if the circulation is restricted to the upper mantle the boundary conditions<sup>20</sup> may produce a circulation whose horizontal scale is considerably greater than its depth (Fig. 3). Hence the horizontal scale is very little guide to the vertical extent of the flow. Nonetheless, the geometry of the anomalies is more easily explained by instabilities of hot lower boundary layer, which exists only if heat is supplied from below. Although the existence of such a boundary layer is required by models in which the flow is confined to the upper mantle, it is possible, though unlikely,

that the unstable layer is as deep as the core-mantle boundary and that a considerable fraction of the heat is supplied from within the core. There is some evidence that models in which all the heat is supplied by internal heating are not compatible with the anomaly distribution, because instabilities can only originate in the upper boundary layer. The presence of large anomalies over the younger but not the older part of the Pacific suggests that the instabilities arise in the lower, not the upper, boundary layer.

We thank R. Rapp for providing the corrected altimetry profiles, and NASA, the Office of Naval Research, the NERC, and the Smithsonian Institution, for grants.

# Vesiculation of mafic magma during replenishment of silicic magma reservoirs

J. C. Eichelberger

Sandia National Laboratories, Albuquerque, New Mexico 87185

*Mafic inclusions are lower in bulk density than the andesitic and dacitic lavas in which they occur, and apparently represent a foam inflated during rapid cooling of wet mafic magma in contact with cooler, more silicic reservoir magma. This process occurs as mafic magma enters the base of the reservoir, so that the mafic/silicic interface becomes unstable in Rayleigh-Taylor fashion. Mixing in these reservoirs thus depends on water content of mafic magma and pressure.*

MAFIC inclusions in andesitic and dacitic lavas and in equivalent plutonic rocks have been interpreted as cumulates from fractional crystallization<sup>1</sup>, restites from deep crustal melting<sup>2</sup> and rapidly crystallized mafic magmatic material generated during magma mixing<sup>3</sup>. The implications of these interpretations for both magmatic and crustal evolution differ dramatically. I have previously argued that the inclusions result from magma mixing on the basis of their texture, bulk composition and phase composition<sup>4-6</sup>. A new observation is that the inclusions exhibit high vesicularity and consequently have a lower bulk density than their hosts. This property is consistent with generation of the inclusions by magma mixing, and may play an important part in the evolution of large magma reservoirs within the upper crust.

## Origin of mafic inclusions

Intermediate composition calc-alkaline volcanic and plutonic rocks commonly contain fine-grained mafic inclusions which appear as dark clots or blobs ranging from a few millimetres to a few tens of centimetres in diameter. Despite differing geological settings of the igneous complexes in which they occur, these inclusions display remarkably uniform textures, compositions and physical properties. In volcanic rocks the inclusions are dominantly plagioclase + hornblende + glass or plagioclase + pyroxene + glass. In plutonic rocks, a felsic matrix is present instead of glass and the dominant mafic phase is usually hornblende or biotite. Several observations indicate that the

inclusions represent mafic magma injected into and chilled within cooler, more silicic magma reservoirs.

(1) Most inclusions are subspherical in shape, unlike accidental xenoliths derived from solid or nearly solid wall rock.

(2) In bulk composition and phenocryst content (typically calcic plagioclase and magnesian olivine) inclusions resemble associated mafic lava. This should not be the case for cumulates, the composition of which is controlled by the crystallizing magma and physical properties of the precipitating phases.

(3) Inclusions have an igneous texture characterized by abundant, elongated, strongly zoned, euhedral crystals in residual glass, indicative of rapid cooling and crystallization to just above solidus. This texture differs from the glassy or micro-crystalline groundmass characteristic of mafic magma quenched at the surface. It also differs from the partial melt texture to be expected in restites.

(4) Some large inclusions exhibit outwards decrease in grain size, increase in elongation of grains, and/or an outer hybrid rind containing reacted or resorbed phenocrysts from the host lava. These observations indicate that the inclusions were chilled against the host, but that both host and inclusions were molten at the same time.

(5) Phenocrysts in the host lava are reacted or resorbed, consistent with heating of reservoir magma during cooling and crystallization of the inclusions.

These observations are further discussed elsewhere<sup>4-6</sup>. Important implications are that crustal magma reservoirs are

**Table 1** Densities of some mafic inclusions and their host lavas\*

\* To obtain bulk density, 0.5–1.0-kg samples of inclusions were separated from host lavas and weighed in air and water. To obtain grain density, these samples were dried and crushed to destroy at least 99% of voids, as indicated by inspection of polished grain mounts. The powder was then weighed in air and water, with the wet measurement made following subjection of the powder to a vacuum for 20 min and addition of water while under vacuum.

maintained by convective transport of heat from the mantle and contain a mixture of components of crustal and mantle derivation<sup>5</sup>.

### Vesicularity of inclusions

Inclusions in lavas contain abundant, fine, evenly distributed vesicles (Figs 1 and 2), even where the host lava contains virtually no vesicles (Fig. 2). Where vesicularity varies within a volcanic unit, as in lava flows with a dense interior and pumiceous surface, vesicularity of inclusions seems to be nearly independent of vesicularity of the host<sup>7</sup>.

Although vesicles are common in extrusive materials, the uniformity in vesicular texture of the inclusions is remarkable. Vesicles in tephra and lavas vary greatly in size and shape (spherical, elongate or irregular) and are sometimes unevenly distributed over distances of 1 cm or less. Vesicles are generally not present in accidental xenoliths. In contrast, vesicular textures in mafic inclusions are consistent not only within a single flow, but among flows of completely unrelated volcanoes (Fig. 1).

Measurement of bulk and grain density of the inclusions (Table 1) shows that this textural similarity is also reflected in

**Fig. 1** Reflected light photomicrographs of mafic inclusions in some andesitic lavas, showing the large proportion of vesicles. *a*, Llao Rock dacite, Crater Lake (Oregon). *b*, Mt Hood andesite (Oregon). *c*, Glacier Peak dacite (Washington). *d*, Chaos Crag dacite, Lassen Volcanic National Park (California). *e*, Nevada Antizana dacite (Ecuador). *f*, Chicoma Mountain dacite, Jemez Mountains (New Mexico). Scale bars: *a*, *d* and *e*, 0.2 mm; and *b*, *c* and *f*, 0.5 mm. Only the vesicles in sample *f* are not filled with epoxy resulting in greater apparent relief. Density data for inclusions *a*, *d* and *f* are reported in Table 1. Transmitted light views are presented in ref. 5.

physical properties. All inclusion samples have a grain density near  $2.8 \text{ g cm}^{-3}$ , because they consist largely of plagioclase and hornblende or pyroxene. Bulk densities are very consistent within a single volcanic unit, and show only a 10% variation from an average for the four volcanoes of  $2.1 \text{ g cm}^{-3}$ . Porosity of the samples ranges from 21 to 33%. Inclusions always have a lower bulk density than their nonvesicular hosts.

Consistency in texture and density relationships suggests that vesicularity of the inclusions may be a primary feature related to their formation and/or incorporation in the host magma. If this is the case and the vesicles, on formation, occupy half or more of the volume fraction observed in the samples, then the inclusions would be buoyant within the magma reservoir. The effect of this phase change on magmatic flow could easily exceed the effect of thermal expansion by an order of magnitude.

### Vesiculation during crystallization

The potential importance of the inclusions to flow within the reservoir means we should evaluate conditions in which the vesicles could be primary. Consider a hot mafic magma which is suddenly brought into contact with a large volume of cooler silicic magma, so that the two magmas are initially in thermal and chemical disequilibrium. The rate at which temperature and concentration of water change towards equilibrium values is proportional to thermal diffusivity ( $K$ ) and chemical diffusivity of water ( $D_{\text{H}_2\text{O}}$ ), respectively. As  $K$  is several orders of magnitude larger than  $D_{\text{H}_2\text{O}}$  (ref. 8), mafic magma quickly reaches thermal equilibrium but not chemical equilibrium with the reservoir, and, therefore, can be regarded as a system open to extraction of heat but initially closed to extraction (or addition) of water. The response of this system to extraction of heat is crystallization. However, only the melt phase can contain

significant amounts of water. The decrease in melt fraction of this system from nearly 1.0 to  $\sim 0.1$  ( $\sim 10\%$  glass by volume observed in inclusions, recalculated vesicle-free) raises the concentration of water in the melt by an order of magnitude. Even for low initial concentrations of water in mafic magma, this enrichment will cause exsolution of a vapour phase at crustal pressures, forming a foam of reduced bulk density. Similar conclusions apply to other possible volatile components, but only water will be considered here, as it is believed to be the dominant volatile component in calc-alkaline volcanism<sup>9,10</sup>.

Cooling can thus cause vesiculation, but the depth at which such a process will be significant strongly depends on volatile content of mafic magma. Bulk density of the mafic foam can be estimated for the water contents and magmatic conditions of interest, because the densities of crystals, melt and water vapour as a function of pressure and temperature, and the solubility of water in melt as a function of pressure, are known or approximately known. Analyses of mafic inclusions and closely associated mafic lavas indicate that the type of mafic magma involved is high alumina basalt or basaltic andesite<sup>1,11,12</sup>. Explosive eruption style, common presence of hornblende phenocrysts, and inferred water content of glass inclusions in phenocrysts indicate that such magmas are volatile-rich, with an estimated water content<sup>13,14</sup> of 3–5 wt% (although some estimates are lower<sup>15</sup>). Figure 3 contrasts bulk density of high alumina basaltic magma containing 3 wt%  $\text{H}_2\text{O}$  during crystallization at 1.5 kbar with the bulk density of similar anhydrous magma. Both systems initially become more dense in response to growth of crystals. However, once vapour saturation occurs in the wet system, continued crystallization causes bubble growth which dramatically lowers bulk density of the magma. Figure 4 shows bulk density of foam formed from basalts with various water contents as a function of pressure at 90% crystallization, the degree of

**Fig. 2** Photomosaics of mafic inclusion in rhyodacitic lava from the Glass Mountain flow, Medicine Lake Highland Volcano, California. The inclusion is predominantly plagioclase and pyroxene with lesser amounts of glass, olivine, and oxides. The host lava is rhyolitic glass with varying amounts of basaltic debris. Scale bar, 1.0 mm. *a*, Reflected light, reveals the abundance of 0.1 mm-diameter vesicles in the inclusion and their scarcity in the host lava. A large vesicle is present at the lava/inclusion interface in the lower portion of *a*. *b*, Transmitted light, shows the mafic character of the inclusion in contrast to the host. Plagioclase crystals within the inclusion and the large vesicle at the interface are apparent. *c*, Taken with transmitted light and crossed polars, shows the crystal-rich character of the inclusion. Density data for these materials are presented in Table 1.

**Fig. 3** Calculated bulk density plotted against degree of crystallization for wet and dry high alumina basaltic magma. The wet curve is for basalt with 3 wt% water at 1.5 kbar. Crystal fraction ( $X_s$ ) is the ratio of crystals to crystals plus melt, by volume:  $X_s = 0$  at the liquidus and  $X_s = 1$  at the solidus. When mafic magma enters a cooler silicic reservoir,  $X_s$  increases with time from near zero until thermal equilibrium is reached near 1. To calculate bulk density as a function of  $X_s$ , the density of the crystal fraction was assumed to be constant at  $2.80 \text{ g cm}^{-3}$ , based on measured values of grain density of inclusions (Table 1) and allowance for thermal expansion<sup>16</sup>. Melt composition was calculated assuming constant crystal fraction composition such that the anhydrous melt composition is rhyolitic<sup>6</sup> at  $X_s = 0.9$ , using an average high alumina basaltic composition<sup>11</sup> for the bulk system. Temperature was assumed to decrease linearly with increasing crystallization ( $X_s$ ) so that  $T = 1,200^\circ\text{C}$  at  $X_s = 0$  and  $T = 900^\circ\text{C}$  at  $X_s = 0.9$ . Melt density was then calculated from melt composition at appropriate temperature and pressure<sup>17</sup>. Vapour fraction of the system was calculated from solubility of water in melt<sup>18</sup> and density of the vapour phase<sup>19</sup>. The calculated bulk density at low to moderate crystallization has uncertainties in assumed conditions, compositions and density of hydrous melt. However, the form of the curve and the bulk density near complete crystallization, which depends mostly on the measured grain density (Table 1) and vapour density, are not significantly affected by these uncertainties. Higher water content or lower pressure result in vapour saturation at lower crystal fraction and greater reduction in bulk density at advanced crystallization.

crystallization observed in the inclusions. Within the range of water contents estimated for high alumina basalts, a significant density decrease accompanies crystallization at mid- to upper-crustal pressures.

## Flotation of foam

It has been argued that the arrangements of vents in andesitic and bimodal volcanic fields, as well as the history and petrology of these fields, indicate episodic replenishment of crustal magma systems by mafic magma from the mantle<sup>5,21-30</sup>. Such magma should initially fill the base of the crustal reservoir, resulting in a stratified system of two fluids. Direct evidence of such stratification, which has been suggested for other types of magma reservoirs<sup>31</sup>, is provided by the compositional zonation of some large tephra sheets, as at Crater Lake<sup>12,32</sup>. The stratification of two fluids is stable if the denser layer is on the bottom. However, Rayleigh-Taylor instability results if the denser layer is on top<sup>33</sup>. Thus, if conditions (volatile content, pressure) permit formation of a mafic foam less dense than the reservoir magma, the interface becomes unstable in Rayleigh-Taylor fashion and blobs of foam will rise into the reservoir magma. Large-scale convection in the reservoir magma driven by heating<sup>8,26,34-36</sup> of, and addition of low density material to, its base would contribute to dispersal of the mafic foam.

From the time that mafic magma enters the reservoir, a foam layer will form at the interface and thicken downwards. The rate of thickening by foam generation is controlled by the thickness of the layer and the rate of removal of foam is controlled by the rise of blobs from the interface (Fig. 5). Inclusion textures indicate that the foam has sufficient crystal content to be cohesive, so it is likely that separation of blobs from underlying material occurs at the base of the foam layer. Furthermore, if the blobs were derived from disaggregation of a large mass many diameters thicker than the inclusions, then a large range of textures representing a large range of cooling rates would be observed. Thus, layer thickness may be comparable with blob diameter. These considerations suggest a dynamic process, in which foam is continually added to a thin layer by downward propagation of a cooling wave and removed from the layer by flotation. For this to be the case, thickening of the foam layer by conduction must approximately balance thinning of the layer by flotation of blobs. A 20-cm layer, the maximum common diameter of inclusions, would thicken at a rate of the order of  $10^{-4} \text{ cm s}^{-1}$  (Fig. 5), close to the rate at which material in the form of blobs 20 cm in diameter and  $2.1 \text{ g cm}^{-3}$  in density ( $\Delta\rho = 0.3 \text{ g cm}^{-3}$ ) would be removed by flotation in  $10^8 \text{ P}$  reservoir magma. Cooling rates for the mafic magma would be of the order of  $10^\circ\text{C h}^{-1}$ . Basalt crystallization experiments have produced textures similar to those of the inclusions, characterized by acicular and skeletal plagioclase, at comparable cooling rates<sup>39,40</sup>. Thus, both the size and texture of the inclusions seem to be consistent with this hypothesized origin.

**Fig. 4** Calculated density plotted against pressure (depth) for mafic foam ( $X_s = 0.9$ ) of various water contents, and measured densities for materials from Medicine Lake lava.  $\rho_x$  and  $\rho_B$  are bulk and grain density of mafic foam, respectively, and  $\rho_R$  denotes density of reservoir magma.  $X_{\text{H}_2\text{O}}$  is weight fraction of water in magma and  $X_V$  is volume fraction of vapour in magma (that is, porosity). Density of reservoir magma ( $\rho_R$ ) with 0 and 1 wt% water<sup>11</sup> at  $T = 900^\circ\text{C}$  was calculated from measured density of lava using data for thermal expansion and compressibility of silicate melt<sup>20</sup>. The possible region for the Medicine Lake volcano magma chamber is shaded, constrained by the conditions that  $\rho_x < \rho_R$  and  $X_{\text{H}_2\text{O}} < 0.05$ . A possible path for magma feeding the chamber is indicated by arrows. —,  $\rho_x$  at constant  $X_{\text{H}_2\text{O}}$ ; ···,  $\rho_x$  at constant  $X_V$ ; ---,  $\rho_R$  at constant  $X_{\text{H}_2\text{O}}$ ; +, measured  $\rho$ ,  $T = 20^\circ\text{C}$ ; ●, calculated  $\rho$ ,  $T = 900^\circ\text{C}$ .

**Fig. 5** Formation of mafic foam (patterned) in the region of the interface between mafic and silicic magma. A cooling wave advances downwards into the mafic magma while foam is removed from the interface by flotation. Within the mafic magma there is an upward transition from mafic liquid below the cooling wave, through less mafic liquid + crystals, to the foam layer, consisting of silicic liquid + crystals + vapour, below the interface. Within the reservoir magma, resorption or reaction of phenocrysts occurs near the interface. The base of the foam layer will be near the isotherm representing  $1/2\Delta T$ . If the interface is kept approximately isothermal by flow of silicic magma (upper limit case for rate of foam formation), then the thickness of the foam layer is  $(Kt)^{1/2}$  and the rate at which it thickens is  $K/2d$  (ref. 37). Using thermal conductivity data<sup>38</sup> and including the effect of crystallization gives  $K = 3 \times 10^{-3} \text{ cm}^2 \text{ s}^{-1}$  so that a 20-cm layer thickens at  $10^{-4} \text{ cm s}^{-1}$ . When the foam layer has grown to this thickness, removal of foam by flotation approximately balances growth of the layer by conduction.

The field of Rayleigh–Taylor instability and hence mixing of mafic material into a silicic reservoir can be defined in terms of water content of basaltic magma and pressure. Much more water is required for flotation of foam at higher pressure because both density of water vapour and solubility of water in melt increase with pressure. Figure 4 shows the possible conditions for mixing in the magma reservoir from which the Medicine Lake dacite of Table 1 erupted. The inference that the inclusions floated constrains depth of the reservoir to  $\leq 15$  km for basalt with 5 wt% water, or 7 km for basalt with 3 wt% water. Data from the other volcanoes studied give similar results. Although volatile content of basalt is a major unknown, the flotation process is clearly limited to magma reservoirs in the upper crust. This conclusion is consistent with the association of foam-bearing lavas with calderas or caldera-like structures, and with the occurrence of analogous intrusive rocks as large, shallowly emplaced plutons.

A possible path of mafic magma feeding such a reservoir is also shown in Fig. 4. The basalt ascends through the crust, slowly becoming less dense with decreasing pressure. As it enters the magma reservoir at 1.5 kbar it is still water unsaturated. As it fills the base of the reservoir, heat is quickly transferred to silicic magma across the large area of the interface so that the mafic magma undergoes rapid crystallization (following the curve in Fig. 3) forming a foam with a bulk density of  $2.25 \text{ g cm}^{-3}$ , and

porosity of 0.19. If this foam remains rigid but leaks after formation, it will follow a constant porosity curve as it flows upwards. If it maintains an equilibrium pore pressure and does not leak, it will follow a constant water curve and blow up during ascent. Obviously, the foam does expand infinitely. As with silicic tephra<sup>41</sup>, growth of vesicles is retarded by increasing viscosity of the residual melt and interference from neighbouring crystals and vesicles. That the inclusions do leak water after their formation is suggested by the common presence of large vesicles at the inclusion/lava interface, as shown in Fig. 2.

## Petrological implications

An important aspect of the problem of silicic magma reservoirs open to replenishment is the stability of the stratification induced by replenishment. In the stable case, any mixing is limited to the very slow process of diffusion across the interface between the two separately convecting magmas. Magma in the reservoir is heated by injection of mafic magma and may, therefore, grow by crustal melting, but it evolves in a manner chemically independent of the primitive magma feeding the chamber. In the unstable case, mixing occurs by rapid transport of mafic material across the mafic/silicic interface and into the convecting reservoir magma. The composition of magma in the reservoir reflects the combined effects of mixing, which makes the magma more mafic, and crustal melting and/or differentiation, which make it more silicic. I suggest that bimodal volcanism represents the stable case, while an important stage in the evolution of andesitic volcanoes and granodioritic batholiths represents the unstable case.

Although these conclusions are based primarily on investigation of certain volcanic rocks of the andesite family, their most important application in terms of volume is to granodioritic batholiths, in which mafic inclusions are a nearly ubiquitous feature. Recent work suggests that most of these inclusions are the plutonic equivalent of the extrusive materials described here<sup>42,43</sup>. If so, these large magma bodies may initially evolve as bimodal systems in the deeper crust, with formation and accumulation of granitic crustal melt in response to basaltic volcanism<sup>44–46</sup>. Subsequent rise of granitic magma bodies into the upper crust within regions of upward flux of wet basaltic magma would result in mixing driven by vapour exsolution, with generation of granodioritic bulk compositions. Direct exsolution of a vapour phase from basaltic magma within upper crustal reservoirs may also play a part in formation of ore deposits, which are sometimes associated with granodioritic intrusives<sup>47</sup>.

I thank B. Daly and F. Harlow of Los Alamos Scientific Laboratory for their help in developing these ideas. This work was conducted at LASL and Sandia National Laboratories (USDOE facilities) with support from the US Department of Energy under contracts W-7405-ENG-36 and DE-AC04-76DP00789, respectively.

# Specific high affinity cell membrane receptors for biologically active phorbol and ingenol esters

Mohammed Shoyab & George J. Todaro

Laboratory of Viral Carcinogenesis, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205

*A variety of normal and transformed avian and mammalian cells and tissues contain high affinity specific receptors on their membranes which interact with biologically active phorbol and ingenol esters in a reversible and saturable manner. The binding of labelled phorbol-12,13-dibutyrate (PDBu) to live or glutaraldehyde-fixed cells is dose-, time- and temperature-dependent. Those phorbol or ingenol esters which stimulate cell growth in culture and have tumour-promoting activity in vivo inhibit the binding of labelled PDBu, while the biologically inactive derivatives fail to do so. Other non-diterpene tumour-promoting agents, epidermal growth factor (EGF), retinoids and prostaglandins do not compete for the binding of labelled PDBu to its specific membrane receptors.*

TUMOUR promoters are compounds which are themselves non-carcinogenic but which can induce tumours in animals previously treated with a suboptimal dose of certain chemical carcinogens<sup>1-5</sup>. Most of the experimental work on tumour promotion has been carried out with phorbol esters, especially 12-*O*-tetradecanoylphorbol esters (TPA), initially isolated from croton oil derived from the seed of the plant *Croton tiglium*<sup>4,6</sup>. TPA and other biologically active phorbol esters elicit and modulate a variety of biochemical and biological responses in mouse skin, including stimulation of macromolecular synthesis, histone phosphorylation, synthesis of phospholipids and modulation of the metabolism of polyamines and cyclic nucleotides<sup>1-5,7-13</sup>. In addition, these compounds induce ultrastructural changes in and affect the differentiation of murine epidermis<sup>7,14</sup>. Tumour-promoting phorbol esters also evoke pleiotypic responses in cultured cells, including the stimulation of macromolecular synthesis and cell proliferation, induction of plasminogen activator and ornithine decarboxylase, loss of surface-associated fibronectin, alterations in the metabolism of cyclic nucleotides and polyamines, stimulation of prostaglandin synthesis, either the inhibition or stimulation of differentiation, and alterations in cell morphology and cell permeability, and elevation in the level of  $[Na^+K^+]ATPase$  activity<sup>1-5,15-23</sup>.

Several biochemical and biological studies provide evidence that the initial site of action of tumour-promoting phorbol esters may be the membrane of target cells<sup>3-5,21,23-26</sup>. The tumour-promoting phorbol esters have been found to modulate the interaction between epidermal growth factor (EGF) and its membrane receptors in a variety of cells in culture<sup>27-29</sup>. The pleiotypic effects of TPA and related tumour promoters *in vivo* as well as *in vitro* seem to mimic the several actions of growth-stimulating polypeptide hormones such as EGF<sup>30</sup> and sarcoma growth factor (SGF)<sup>31</sup>. However, the effect, though rapid in modulating the EGF receptors, is indirect as it cannot be shown using low temperatures<sup>26</sup> and/or fixed cells or in isolated cell membranes (unpublished results). This would suggest that TPA produces its membrane effects through an interaction distinct from the EGF receptor interaction.

<sup>3</sup>H-TPA has been reported to bind to HeLa cells in a non-saturable, noncompetitive and nonspecific fashion<sup>32</sup>. We find that <sup>3</sup>H-TPA binds to a variety of fibroblastic and epithelioid cells in saturable and reversible manner but these binding sites for TPA seem to be numerous ( $30 \times 10^6$  per cell) and of low affinity ( $K_d = 10^{-7}$  M). We have used <sup>3</sup>H-PDBu to characterize the binding sites of phorbol and ingenol esters. PDBu is a phorbol ester which is highly active *in vivo* and *in vitro* but is

comparatively less lipophilic than TPA<sup>4,33</sup>. Thus, PDBu would partition in membrane lipids much less than TPA and lead to less nonspecific binding. Recently, <sup>3</sup>H-PDBu binding to a particulate fraction of chicken embryonic fibroblasts has been reported<sup>34</sup>.

## Binding of PDBu to Cells

Figure 1 describes the binding of <sup>3</sup>H-PDBu ( $19.7 \text{ ng ml}^{-1}$ , specific activity  $6.4 \text{ Ci mmol}^{-1}$ , Life System Co., Newton, Massachusetts) to live and fixed mink lung cells (CCL 64)<sup>35</sup> and BALB/3T3 clone A31 cells (CLL 163)<sup>36</sup> at 23 °C, and the competition of binding of labelled PDBu to cells with unlabelled PDBu. The live and the fixed mink cells bound 2,155 and 1,987 c.p.m., respectively, whereas live and fixed A31 cells bound 3,605 and 3,419 c.p.m., respectively, of <sup>3</sup>H-PDBu per  $10^6$  cells in the absence of unlabelled PDBu. As the concentration of unlabelled PDBu was increased, the binding of <sup>3</sup>H-PDBu to both types of cells decreased. Figure 1 shows that viable and glutaraldehyde-fixed mink cells required 30–35  $\text{ng ml}^{-1}$  of PDBu for 50% inhibition of binding; the A31 showed  $ID_{50}$ s of 65–70  $\text{ng ml}^{-1}$  and, again, no difference between viable and fixed cells.

Figure 2a shows the extent of binding of <sup>3</sup>H-PDBu to mink lung cells at various temperatures, as a function of incubation time. The binding increased linearly for 15 min at 4 °C, whereas binding at 23 °C and 37 °C was linear for only a few min. Maximal binding was achieved within 7.5 min at 37 °C and started to decrease with increasing incubation time. The saturation of the binding of labelled PDBu to cells at 23 or 4 °C was observed between 20–40 and 90–120 min, respectively. When <sup>3</sup>H-PDBu-labelled mink lung cells (23 °C, 30-min incubation) containing bound <sup>3</sup>H-PDBu were incubated in only binding buffer at 4, 23 or 37 °C, bound radioactivity dissociated from cells and was released into the medium in a time- and temperature-dependent manner (Fig. 2b).

Optimum binding of PDBu was achieved at pH 6.7. The binding was found to be linear up to  $12 \times 10^6$  cells  $\text{ml}^{-1}$  (23 °C, 20-min incubation). It was not significantly affected by hydroxyurea (10 mM), actinomycin D ( $10 \mu\text{g ml}^{-1}$ ), cycloheximide ( $10 \mu\text{g ml}^{-1}$ ) or sodium fluoride (1 mM). Thus, it seems that PDBu binding to its receptors does not require DNA, RNA or protein synthesis, or metabolic energy. We did not find any absolute requirements of metal ions for PDBu binding to cells; however, metal chelating agents (EDTA and EGTA) at 5 mM concentration reduced the binding to approximately 50%.  $Mg^{2+}$ ,  $Co^{2+}$ ,  $Na^+$  and  $K^+$  did not significantly affect the binding

although  $Mn^{2+}$ ,  $Ca^{2+}$  and  $Zn^{2+}$  significantly stimulated the binding of  $^3H$ -PDBu to mink cells.

Sub-cellular distribution of bound  $^3H$ -PDBu to mink cells ( $4^\circ C$  for 30 min or  $23^\circ C$  for 10 min) revealed that approximately 80% of labelled PDBu bound to the membranous fraction. This result and the comparable binding of  $^3H$ -PDBu to fixed or live cells suggest that the binding sites are located on the plasma membranes of cells.

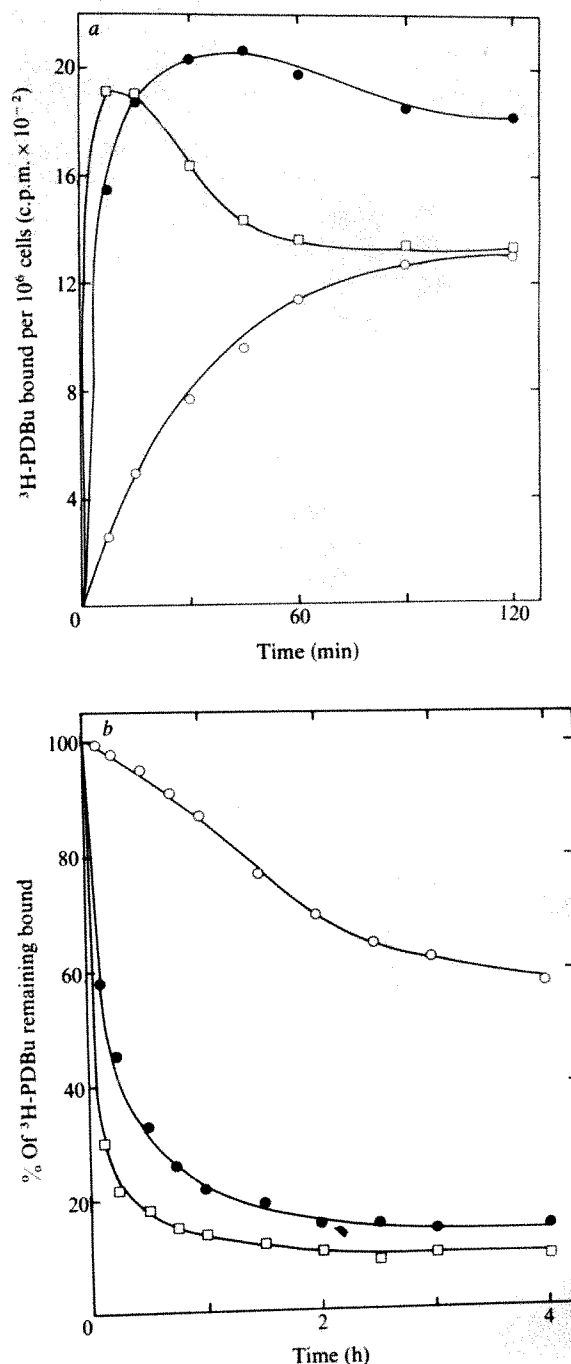

### Wide distribution of PDBu binding sites in cell cultures and various murine tissues

Table 1 shows the specific binding of  $^3H$ -PDBu to various normal cell lines from different species in culture and murine cell lines transformed by RNA tumour viruses, DNA tumour viruses, SV40 and polyoma or by chemical carcinogens, benzo-pyrene (BP) and methylcholanthrene (MC). PDBu bound to murine (normal or transformed), rat, cat, mink, hamster, rabbit, bat, dog, monkey, human and chicken cells. The transformed murine cells were found to bind more PDBu than their normal counterparts.  $^3H$ -PDBu also bound to Kirsten sarcoma virus transformed murine cells as well as to Swiss/3T3 clone NR-6; both cell lines lack EGF receptors<sup>37,38</sup>. The specific binding sites are also present in murine brain, spleen, thymus, lung, skin, kidney, heart, thigh muscle, liver and intestine in decreasing order. The murine brain which lacks EGF receptors and spleen

has an exceptionally high number of receptors for PDBu. Neither human nor mouse erythrocyte bound detectable amounts of  $^3H$ -PDBu. Thus, the PDBu binding sites are widely distributed and are distinct from EGF binding sites.

**Fig. 1** Binding of  $^3H$ -PDBu to live and fixed cells and inhibition of  $^3H$ -PDBu binding by unlabelled PDBu. The cells were grown in 850 cm<sup>2</sup> roller culture bottles (RCB) in Dulbecco's minimum essential medium (DMEM) containing 10% calf serum (CS). Approximately 70% confluent cells were used for the binding assays. The medium was aspirated from bottles, cells were washed twice with 50 ml of binding buffer (BB) consisting of DMEM containing bovine serum albumin (BSA, 1 mg ml<sup>-1</sup>) and *N,N*-bis-(2-hydroxyethyl)-2-amino-ethane-sulphonic acid (BES, 5 mM), adjusted to pH 6.8. The cells were scraped in 25 ml of BB per RCB and transferred to plastic tubes and pelleted in a refrigerated centrifuge. The cell pellets were suspended in BB and an aliquot used to determine cell number in a Coulter counter. The binding assays were performed in duplicate in 12 × 75 mm disposable glass culture tubes (Kimax). The binding mixture contained 5 ng  $^3H$ -PDBu ( $\sim 4 \times 10^4$  c.p.m.), 0–5  $\mu$ g of unlabelled PDBu, 0.5% final concentration of dimethyl sulphoxide (DMSO) and  $1 \times 10^6$  cells in a total volume of 0.25 ml BB. After incubation for 30 min at  $23^\circ C$ , 4 ml cold BB was added to each tube, the contents mixed and tubes were centrifuged for 4 min at  $4^\circ C$  at 1,000g to pellet the cells. The supernatant solution was carefully drained off, the pellet was suspended in 4 ml of cold BB and transferred to other tubes. Tubes were again centrifuged as earlier, supernatant solution was removed and cell pellets solubilized in 0.7 ml of lysing buffer (0.01 M Tris-HCl, pH 7.4, containing 0.5% SDS and 1 mM EDTA). The mixture was transferred to counting vials and 10 ml of Optigel (Melay Laboratories) was added to each vial. The vials were vigorously shaken and radioactivity determined using a Beckman beta counter. For binding assays with fixed cells, the medium was aspirated, cells were washed twice with cold PBS and scraped from RCB and transferred to plastic tubes and pelleted. The pellet was suspended in 2% glutaraldehyde, pH 7.4 (1 ml per  $10^6$  cells) for 2 h at  $4^\circ C$ . After this period, cells were pelleted and washed twice with cold PBS and the final pellet was suspended in BB. The binding with fixed cells was performed as described for the live cells.  $\circ$ , Live mink lung cells;  $\bullet$ , fixed mink lung cells;  $\square$ , BALB/3T3-A31 cells;  $\blacksquare$ , fixed BALB/3T3-A31 cells.

**Fig. 2** a, Effect of incubation time and temperature on  $^3H$ -PDBu binding to mink lung cells. The binding assays were performed in duplicate as in Fig. 1 legend, in the presence or absence of  $20 \mu$ g ml<sup>-1</sup> unlabelled PDBu. The radioactivity bound to cells in the presence of  $20 \mu$ g ml<sup>-1</sup> unlabelled PDBu was considered to be nonspecific binding and all data were corrected accordingly.  $\circ$ ,  $4^\circ C$ ;  $\bullet$ ,  $23^\circ C$ ;  $\square$ ,  $37^\circ C$ . b, Dissociation of bound  $^3H$ -PDBu from mink lung cells. Binding of  $^3H$ -PDBu (30 min at  $23^\circ C$ ) was performed as described in Fig. 2a legend. After the final washing, cells were suspended in BB (0.25 ml per  $10^6$  cells) and duplicate mixtures were incubated at each indicated temperature for each indicated time. After incubation, 4 ml of cold BB was added to each tube, cells were mixed and pelleted as described in Fig. 1 legend. The supernatant solutions were removed, pellets suspended in the lysing buffer and counted as in Fig. 1 legend. The nonspecific binding was corrected as in a.  $\circ$ ,  $4^\circ C$ ;  $\bullet$ ,  $23^\circ C$ ;  $\square$ ,  $37^\circ C$ . The released labelled material was analysed by HPLC and was found to be PDBu.

**Table 1** Binding of  $^3\text{H}$ -PDBu to cells of various species

| Species | Cells                                   | $^3\text{H}$ binding<br>(c.p.m. per<br>$10^6$ cells) |

|         | Erythrocytes                            | 12   |

The binding assays were performed as in Fig. 1 legend. The nonspecific binding was corrected as described in Fig. 2 legend.

### Saturability of PDBu Binding

The effect of PDBu concentration on PDBu binding to mink lung cells and murine BALB/3T3-A31 cells is shown in Fig. 3. PDBu binding was found to be linear up to a PDBu concentration of about  $5 \text{ ng ml}^{-1}$  for both cell types. As the concentration of PDBu was increased beyond  $5 \text{ ng ml}^{-1}$ , the binding of PDBu to cells gradually began to deviate from linearity and started to level off. PDBu binding sites were almost saturated at a PDBu concentration of  $200 \text{ ng ml}^{-1}$  (Fig. 3, insets). Figure 3 also includes Scatchard plots of PDBu binding to mink lung cells and to BALB/3T3 cells. These data produced almost linear plots for both cell types. At saturating concentration of PDBu, approximately  $2.0 \times 10^5$  molecules bound to mink lung cells and  $5.1 \times 10^5$  molecules to BALB/3T3 cells. The apparent  $K_d$  values were calculated to be  $1.3 \times 10^{-9} \text{ M}$  for mink lung cells (Fig. 3a) and  $0.9 \times 10^{-9} \text{ M}$  for BALB/3T3 cells (Fig. 3b). The apparent  $K_d$  value for EGF interaction to its receptors on both cell types has been reported to be  $0.5 \times 10^{-9} \text{ M}$  (ref. 28). Thus, the affinity of PDBu for its receptors is in the same range as that of EGF receptors for its ligands and other ligands for their receptors<sup>28</sup>.

### Relationships between structure of phorbol and ingenol derivatives and binding to mink lung cells

There are now available several natural and synthetic analogues of phorbol and ingenol with various degrees of promoting activity in the two-stage tumorigenesis model<sup>1-5</sup>. We studied their effects on inhibiting the binding of  $^3\text{H}$ -PDBu to mink lung cells (Fig. 4 and Table 2). TPA was the most potent competitor of PDBu binding among the phorbol, ingenol and mezerein derivatives tested. The dose required for 50% inhibition of PDBu binding to cells for TPA, PDBu, phorbol-12,13-didecanoate (PDD), phorbol-12,13-dibenzoate (PDB), 12-deoxyphorbol-13-tetradecanoate (DPTD), ingenol-13-hexadecanoate (IHD), mezerein (MZ), phorbol-12,13-diacetate (PDA) and ingenol 3,5,20-triacetate (ITA) were  $9.6 \times 10^{-9} \text{ M}$ ,  $9.9 \times 10^{-8} \text{ M}$ ,  $13.4 \times 10^{-8} \text{ M}$ ,  $18.2 \times 10^{-8} \text{ M}$ ,  $2.4 \times 10^{-8} \text{ M}$ ,  $5.8 \times 10^{-8} \text{ M}$ ,  $7.2 \times 10^{-8} \text{ M}$ ,  $6.4 \times 10^{-6} \text{ M}$  and  $9.8 \times 10^{-6} \text{ M}$ , respectively; 4  $\alpha$ -PDD, 4-O methyl-TPA (MeTPA), phorbol and ingenol had negligible effects on PDBu binding (Fig. 4a, b). The relative potency of these agents in competing EGF binding was: TPA > DPTD > IHD > MZ > PDBu > PDD > PDB > PDA > ITA > Me-TPA > 4  $\alpha$ -PDD > phorbol > ingenol (Table 2). The inhibition of PDBu binding to its receptors by different phorbol and ingenol derivatives correlated very well with their tumour-promoting activity. Table 2 also summarizes the dose required for 50% inhibition of EGF binding for various phorbol derivatives (data taken from ref. 28) and for ingenol derivatives and MZ (unpublished data).  $2 \text{ ng ml}^{-1}$  of  $^{125}\text{I}$ -EGF and  $19.7 \text{ ng ml}^{-1}$  of  $^3\text{H}$ -PDBu were used in these binding experiments. Table 2 shows that ID values for PDBu binding and for the indirect effect on EGF binding, as well as calculated  $K_i$  values for PDBu binding and EGF binding for the various agents correlated very well with each other and with their tumour-promoting potential. The relative values ( $\text{ID}_{50}/K_i$ ) for various agents were found to be almost similar.

### Lack of competition of PDBu binding by non-diterpene ester tumour promoters and by certain other compounds

Non-diterpene ester tumour promoting agents such as phenol, iodoacetic acid, iodoacetamide, bile acids, barbiturate, oleate, laurate, limonene, canthradin, anthradin, saccharin, or cyclamate<sup>1-5</sup>, did not affect the binding of  $^3\text{H}$ -PDBu to its receptors even up to a concentration of  $10 \mu\text{g ml}^{-1}$ . However, anthralin, another tumour promoter, actually enhanced the binding of PDBu to mink lung cells (Table 3). Thus, it seems that non-diterpene ester tumour promoting agents do not exert their biological effect through these membrane receptors. Retinoic

**Table 2** Correlation between the potency of phorbol and ingenol derivatives for promoting skin tumours and their ability to inhibit the binding of  $^3\text{H}$ -PDBu or  $^{125}\text{I}$ -EGF to cells

\* Values derived from Fig. 4.  $19.7 \text{ ng ml}^{-1}$  of  $^3\text{H}$ -PDBu was used for binding.

<sup>†</sup> Values for phorbol derivatives are taken from ref. 28. The values for DPTD, MZ and ingenol derivatives are from our unpublished results.  $2 \text{ ng ml}^{-1}$  of  $^{125}\text{I}$ -EGF were used for binding.

<sup>‡</sup>  $K_i$  values were calculated according to method of Cheng and Prusoff<sup>42</sup>, using the equation  $K_i = \text{ID}_{50} \times 1/(1 + L/K)$ , where  $L$  and  $K$  denote concentration and affinity of labelled probe.

acid, dexamethasone, prostaglandins and disulfiram are reported to inhibit tumour promotion<sup>1-5</sup>. None of these reagents significantly modulated the binding of PDBu to mink lung cells (Table 3). These results suggest that these reagents inhibit tumour promotion by acting at some site other than the receptors for phorbol or ingenol esters. In addition, cholera toxin, diphtheria toxin, oxytocin, vasopressin, gramicidin, monensin, melittin, digitonin, filipin, amphotricin, kanacidin, ganglioside, nystatin, cholesterol and lysophosphocholine, up to a concentration of  $10 \mu\text{g ml}^{-1}$ , did not significantly affect the binding of labelled PDBu to its receptors.

The binding of PDBu to mink cells is not inhibited by EGF even up to a concentration of  $10 \mu\text{g ml}^{-1}$  (Table 3). Although biologically active diterpene esters efficiently modulate EGF

The binding assays were performed as in Fig. 1 legend. The nonspecific binding was corrected as in Fig. 2 legend.

receptor interaction in this cell<sup>28</sup>, PDBu binds to cells lacking EGF receptors (Table 1). The binding of PDBu to cells does not correlate with their EGF receptor numbers. These experiments clearly demonstrate that membrane receptors which specifically interact with phorbol or ingenol diterpene esters are structurally and functionally distinct from EGF membrane receptors.

## Discussion

These experiments demonstrate the existence of high affinity sites on avian, mammalian and primate cells in culture which specifically interact with biologically active phorbol and ingenol derivatives but not with biologically inert analogues of these diterpenes. PDBu binding to its receptors exhibits specificity, saturability, and reversibility. PDBu-binding sites in cell membranes are different from EGF membrane receptors as PDBu also binds to cells which lack EGF receptors. In contrast to the modulation of EGF binding to its receptors by biologically active phorbol or ingenol esters, EGF does not influence the interaction between PDBu and its membrane receptors. These membrane receptors specifically bind biologically active phorbol and ingenol esters but not other non-diterpene ester tumour promoters. Potent inhibitors of tumour promotion such as retinoids, anti-inflammatory steroids, prostaglandins and cyclic nucleotides do not interact with these receptors. Inter-

tingly, anthralin, a non-diterpene tumour promoter, increases the binding of PDBu to mink cells in a dose-dependent manner. We do not know whether anthralin exhibits this effect by increasing the binding capacity or the binding affinity or both, or acts by some other mechanism. Whether anthralin enhances the tumour-promoting activity of PDBu and other related compounds should be investigated.

Thus, why should mammalian cells have specific receptors for biologically active phorbol and ingenol ester compounds of plant origin? TPA and certain analogues may have some structural resemblance to the endogenous growth-promoting and/or differentiation-modulating substance(s) (agonists and/or antagonists) that have specific membrane receptors. These compounds recognize and interact with the receptors, mimicking the action of the putative substance(s). Azaserine, cordycepin, curare, opiate, physostigmine, plant lectins, puromycin and tubercidin appear to exert their action by such biological mimicry<sup>39-41</sup>. Rohrschneider and Boutwell have suggested that TPA bears some similarity to a polyunsaturated fatty acid ester (PUFA), or a metabolite of it, and might exert its effects by interacting with PUFA receptors<sup>39</sup>. The binding of PDBu to fixed cells suggests that it interacts with the cellular components (receptors) located on the plasma membranes of the cells. The isolation and further characterization of PDBu receptors and putative endogenous ligand(s) should help in understanding tumour promotion.

# An actin-binding protein from *Acanthamoeba* regulates actin filament polymerization and interactions

Gerhard Isenberg, Ueli Aebi & Thomas D. Pollard

Department of Cell Biology and Anatomy, The John Hopkins University School of Medicine, Baltimore, Maryland 21205

*A protein has been purified from Acanthamoeba which, like cytochalasin B, caps the end of actin filaments normally favoured for monomer addition and inhibits the interactions of actin filaments. In addition, this 'capping' protein nucleates the polymerization of actin monomers and blocks the annealing of actin filament fragments.*

REGULATION of actin filament polymerization and actin filament interactions seems to be essential for cellular motility and the maintenance of cytoplasmic consistency. Thus, cells must have mechanisms to specify actin filament number, length, stability and sites of formation, in addition to mechanisms which regulate the interactions of the filaments with each other, with membranes and with other cellular structures such as microtubules. These mechanisms are just beginning to be understood<sup>1</sup>.

The number and length of the actin filaments could be limited partly by the concentration of polymerizable monomer and the number of filament nucleating sites. The concentration of actin monomer may be controlled by profilin<sup>2</sup>, a ubiquitous small protein which binds actin monomer and inhibits polymerization<sup>2,3</sup>, or by other unrecognized mechanisms which also sequester actin monomers. Even less is known about cellular nucleating mechanisms, because nucleating molecules have not previously been identified. However, electron microscopy

clearly shows that there are structures, such as the dense tips of microvilli<sup>4</sup> and sperm actomeres<sup>5</sup>, which can specify both the site and polarity of polymerization.

A more specific mechanism for controlling filament length would be to cap one or both ends with specific proteins. In striated muscle a protein named  $\beta$ -actinin may block the 'pointed' end of the thin filaments<sup>6</sup>. (The terms 'barbed' and 'pointed' are used to specify the polarity of actin filaments which is revealed by the arrowhead-shaped complexes formed when myosin binds to the filament<sup>7</sup>. The barbed end is the fast, and the pointed end the slowly polymerizing end<sup>8</sup>.) There have been disagreements about the identification of the molecule<sup>6,9</sup>, but a preparation consisting of polypeptides of molecular weights (MWs) 34,000 and 37,000 is a potent inhibitor of the annealing of sonicated actin filament fragments<sup>6</sup>. Non-muscle cells also have proteins which can limit actin filament length, presumably by acting on the end(s) of the filaments. In *Physarum* the protein is called plasmodium actinin and has a molecular weight of 43,000 (refs 10, 11). In macrophages the length-regulating protein, gelsolin, is calcium sensitive and has a MW of 90,000 (ref. 12).

Actin filaments can interact with each other by both cytochalasin-insensitive connections by multivalent actin-binding proteins<sup>13-16</sup> and by cytochalasin-sensitive direct associations between filaments<sup>17,18</sup>. Gels consisting of random networks of filament form when the number of cross-links is low<sup>16</sup>, whereas bundles of aligned filaments form when the number of cross-links is high<sup>15</sup>. The regulation of these interactions could, in principle, occur at three levels: the formation and breakdown of

**Fig. 1** Purification of the actin filament capping protein from *Acanthamoeba*. The material obtained at each step of the purification was assayed for its ability to inhibit the low-shear apparent viscosity<sup>16</sup> of pure actin filaments and for polypeptide composition by gel electrophoresis in 7.5% polyacrylamide with 0.1% sodium dodecylsulphate<sup>16</sup>. The viscometric assay was carried out by polymerizing a mixture of 0.5 mg ml<sup>-1</sup> gel-filtered muscle actin monomers<sup>18</sup> with the material to be tested in a buffer consisting of 10 mM imidazole, 2 mM MgCl<sub>2</sub>, 1 mM EGTA, 1 mM ATP, pH 7.5, in a 1.2-mm inside-diameter capillary tube for 10 min at 25°C. A 0.64-mm outside-diameter stainless steel ball was then rolled down the wall of the capillary tilted at 50° from horizontal. The apparent viscosity was calculated from the ball velocity by comparison with newtonian standards<sup>16</sup>. The horizontal dashed line is the viscosity of actin filaments alone. Actomyosin supernatant (□) was obtained as described<sup>22</sup> and the fraction precipitating between 1.5 and 2.5 M ammonium sulphate (Δ) collected and dialysed against ID buffer (20 mM imidazole, 0.5 mM dithiothreitol (DTT), pH 7.5) with 1 mM EGTA. The ammonium sulphate fraction was further purified by gel-permeation chromatography on a 4 × 95-cm column of Sephadex G-150 in the same buffer. The peak of the viscosity-inhibiting activity (▲) was then applied to a 2.5 × 19-cm column of hydroxylapatite equilibrated with ID buffer and eluted with a concave 0–250 mM phosphate gradient. The peak of viscosity-inhibiting activity (○) was dialysed against ID buffer and finally purified by chromatography on a 1.5 × 7.5-cm column of DEAE-cellulose equilibrated with ID buffer and eluted with a linear 50–300 mM KCl gradient. The purified capping protein eluted at 200 mM KCl (●) and consisted of two major polypeptides (of MWs 28,000 and 31,000) and a minor 60,000-MW polypeptide (arrowheads).

**Fig. 2** Effect of filament capping protein on the polymerization kinetics of pure actin. Polymerization was monitored by measuring the high-shear viscosity in an Ostwald capillary viscometer<sup>18</sup>. *a*, Gel-filtered pure actin monomer (0.5 mg ml<sup>-1</sup>) was mixed with 0 (●), 0.44 μg ml<sup>-1</sup> (○), 1.54 μg ml<sup>-1</sup> (□) or 3.08 μg ml<sup>-1</sup> (Δ) of capping protein and polymerized in 2 mM MgCl<sub>2</sub>, 10 mM imidazole, 1 mM EGTA, 1 mM ATP, pH 7.5, at 25°C. *b*, Gel-filtered actin monomer (0.5 mg ml<sup>-1</sup>) (●) was mixed with 2.2 μg ml<sup>-1</sup> capping protein (Δ), 30 μg ml<sup>-1</sup> actin filaments (○) or 2.2 μg ml<sup>-1</sup> capping protein plus 30 μg ml<sup>-1</sup> actin filaments (□) and polymerized in 20 mM KCl, 10 mM imidazole, 0.7 mM Tris, 0.07 mM ATP, 0.2 mM DTT, 0.07 mM CaCl<sub>2</sub>, pH 7.5, at 25°C. *c*, Steady-state samples of 0.5 mg ml<sup>-1</sup> actin filaments in the buffer described in *b* were mixed with 0 (●), 2.2 μg ml<sup>-1</sup> (○), 4.4 μg ml<sup>-1</sup> (□) or 8.8 μg ml<sup>-1</sup> (Δ) of capping protein and sonicated for 15 s at setting 1 of a Branson sonicator. The recovery of viscosity was followed at 25°C.

the actin filaments<sup>19</sup>; the cross-linking of filaments by actin-binding proteins<sup>13-16</sup>; and the modulation of actin filament self-associations<sup>16</sup>. This last possibility has not been considered seriously before, but the cell might well need to regulate actin filament self-associations, because they are sufficiently strong for the viscosity of pure actin filament solutions to approach infinity at the low shear rates found in cells<sup>20</sup>. The existence of an endogenous cytochalasin-like factor could explain why cytoplasm is not solid. Such a protein factor contaminates conventional muscle actin preparations<sup>18,21</sup>. This unpurified factor strongly inhibits actin filament self-associations without inhibiting polymerization<sup>21</sup>.

We have purified and characterized an actin filament 'capping protein' from *Acanthamoeba* and suggest that it may play a central role in the regulation of both actin filament polymerization and cross-linking.

## Purification of the capping protein

As the capping protein inhibits the low shear viscosity of pure actin filaments, we used a low-shear (<10 s<sup>-1</sup>) falling-ball viscometer<sup>16</sup> to assay the capping protein during purification. As the first step, crude *Acanthamoeba* extracts were fractionated on DEAE-cellulose as described previously<sup>16</sup>. The fractions containing the overlapping peaks of viscosity-inhibiting activity<sup>16</sup>, myosin-2 and actin were pooled and actomyosin-2 precipitated<sup>22</sup>. The resulting supernatant, which contained most of the viscosity-inhibiting activity, was used as the starting material to purify capping protein to near homogeneity. The purification steps included ammonium sulphate precipitation, and gel permeation, hydroxylapatite and ion-exchange chromatography (Fig. 1). The small amount of capping protein which precipitated with the actomyosin-2 could be recovered as a by-product of myosin-2 purification by the method of Pollard *et al.*<sup>22</sup>.

The purified protein from four different preparations consisted of two major polypeptides with MWs 28,000 and 31,000 and a variable minor polypeptide of MW 60,000. The inhibitory activity is probably associated with the polypeptides of MWs 28,000 and 31,000 because they were present in proportion to inhibitory activity over the final DEAE peak, and because the minor contaminants including the 60,000-MW polypeptide

were also present in neighbouring fractions without inhibitory activity.

As shown in Fig. 1, the specific inhibitory activity of the fractions increased about 50-fold during purification of the two polypeptides by more than 100-fold, suggesting that the protein was partially inactivated during purification. The presence of some gelation-factor activity in the crude fractions (Fig. 1) made calculation of yields somewhat difficult, but we estimated the overall yield to be ~10%. In terms of mass, we obtained ~4  $\mu\text{g}$  of purified capping protein per g of wet cells.

### Physical properties of the capping protein

The two polypeptides constituting the purified protein were present in the ratio of 1.5 (31 K) to 1 (28 K) judging from the intensities of the two bands on Coomassie blue-stained electrophoretic gels. In addition there was ~10% of a 60 K polypeptide. The Stokes' radius of native capping protein was 4.0–4.4 nm measured by the method of Ackers<sup>23</sup> using gel-permeation chromatography in either 20 mM imidazole or 0.6 M KCl. A spherical protein of this size would have a molecular weight of about 120,000 to 160,000. Thus the native protein could consist of up to two copies each of the two polypeptides. The capping protein is soluble in both low and high ionic strength buffers at neutral pH, but its activity is more stable in 50 mM KCl than in 20 mM imidazole alone. The absorption spectrum of the capping protein has a maximum at 277 nm and a minimum at 250 nm. The extinction coefficient at 280 nm is ~0.86  $\text{cm}^{-1} \text{ml mg}^{-1}$ .

### Binding of capping protein to actin filaments

Capping protein does not pellet by itself, but binding to actin filaments was demonstrated in experiments where 4.8  $\mu\text{g}$  capping protein (6  $\mu\text{g}$  total) pelleted at 150,000g for 45 min with 500  $\mu\text{g}$  of actin filaments in 2 mM  $\text{MgCl}_2$ . Although binding has not been studied in any detail, this did not represent saturation of capping protein binding sites, because 7.2  $\mu\text{g}$  capping protein (12  $\mu\text{g}$  total) pelleted with the same amount of actin.

### Effect of capping protein on actin filament polymerization

The polymerization of purified actin monomers consists of a slow nucleation step followed by a rapid elongation step<sup>24</sup>. We measured the rate and extent of polymerization in an Ostwald capillary viscometer with a high shear rate ( $>1,000 \text{ s}^{-1}$ ) which disrupts weak associations between the filaments, making the observed viscosity largely a function of polymer concentration and length distribution. In 20 mM KCl the nucleation step was very slow as shown by the 40-min lag in the time course of the viscosity change for actin monomer alone (Fig. 2b). The elimination of this lag by added actin filaments confirmed that it was due to nucleation (Fig. 2b). The rapid rise in viscosity after nucleation was due to elongation of the filaments. In 2 mM  $\text{MgCl}_2$  both of these steps were faster (Fig. 2a).

Purified capping protein had a complex effect on actin polymerization. Paradoxically, it both promoted nucleation and inhibited the rate of growth of actin filaments (Fig. 2a,b). These effects were most apparent in conditions where polymerization was slow, such as 20 mM KCl, where very low concentrations of capping protein eliminated the lag phase (Fig. 2b). This demonstrated stimulation of nucleus formation. In 2 mM  $\text{MgCl}_2$  the lag was short, but high concentrations of capping protein clearly increased the initial rate of the viscosity change and altered the shape of the curve from sigmoidal to hyperbolic (Fig. 2a).

Although capping protein promoted nucleus formation, it was, at the same time, a potent inhibitor of the rate of actin filament elongation. This inhibition was seen in mixtures of capping protein with pure actin monomers (Fig. 2a,b), but is best illustrated by experiments in which actin monomer polymerization was nucleated by actin filament fragments. The rate

of the viscosity change in the absence of capping protein was much greater than the rate in the presence of capping protein (Fig. 2b).

By observing the direction and extent of actin filament growth at the ends of decorated nuclei (Fig. 3), we found that capping protein inhibited filament elongation by blocking monomer addition at the barbed end of the filaments (Fig. 3). As established previously<sup>8</sup> actin filaments normally grow bidirectionally with a strong bias for the barbed end (Fig. 3a). In the presence of low concentrations of capping protein, monomer added to the pointed end, but there was no growth at the barbed end (Fig. 3b). Capping protein also blocked monomer addition to the barbed end of actin filaments in the presence of 5 mM  $\text{MgCl}_2$ , 75 mM KCl and 0.16 mM ATP. This was shown in monomer addition experiments using demembrated microvillus cores<sup>25</sup>. The rates of growth at the pointed end with capping protein were 1 molecule per s in 20 mM KCl and 6  $\mu\text{M}$  actin, and 6 molecules per s in Mg-KCl and 3  $\mu\text{M}$  actin. These rates were similar to normal growth rates at the pointed end.

The capping protein also inhibited the extent of annealing of actin filaments fragmented by sonication (Fig. 2c). The steady-state viscosity is reduced in a concentration-dependent fashion, but the rate of the approach of the viscosity to the steady state was hardly affected.

**Fig. 3** Effect of filament capping protein on the polarity of actin filament polymerization in 20 mM KCl. The direction of polymerization was determined electron microscopically by adding actin monomers to short actin filaments decorated with an equimolar amount of muscle myosin subfragment-1 which acted as nuclei. These decorated nuclei were reduced in length by passage through a syringe needle. Samples for electron microscopy were negatively stained with 0.75% uranyl formate, pH 4.3. Scale bar, 100 nm. *a*, Control. 50  $\mu\text{g ml}^{-1}$  decorated actin nuclei were incubated for 5 min at 22 °C with 100  $\mu\text{g ml}^{-1}$  actin monomer freshly prepared by gel filtration in ATP-free buffer<sup>18</sup>. The bare filament growth is predominantly from the barbed end of the decorated nuclei. *b*, Effect of capping protein. 50  $\mu\text{g ml}^{-1}$  decorated nuclei were incubated with 150  $\mu\text{g ml}^{-1}$  ATP-free monomer and 2.2  $\mu\text{g ml}^{-1}$  capping protein for 30 min at 22 °C. Note the absence of barbed-end growth and the short bare filaments at the pointed end.

**Table 1** Effect of filament capping protein on the steady-state polymer concentration

| Capping protein ( $\mu\text{g ml}^{-1}$ ) | Supernate actin monomer ( $\mu\text{g ml}^{-1}$ ) | Calculated polymer ( $\mu\text{g ml}^{-1}$ ) | Specific viscosity (cS) | Reduced viscosity (cS per mg polymer per ml) |
|---|---|--|-------------------------|--|
| 0   | 34  | 466  | 0.42                    | 0.90   |
| 0.44                                      | 59  | 441  | 0.38                    | 0.86   |
| 1.54                                      | 128   | 372  | 0.37                    | 0.99   |
| 3.08                                      | 136   | 364  | 0.32                    | 0.88   |

Steady-state polymerized actin samples from the experiment in Fig. 2a were centrifuged for 20 min at  $10^5$  r.p.m. in a Beckman Airfuge at 22 °C. Actin filaments pellet in 5 min in these conditions. The fraction of unpolymerized actin in the supernate was determined by quantitative gel electrophoresis. The concentration of polymer was calculated by difference.

The filament capping protein reduced the steady-state high-shear viscosity in a concentration-dependent fashion (Fig. 2). This seemed to be due primarily to a reduction in polymer concentration (Table 1), because the reduced viscosity per mg polymer was not altered significantly by the presence of the capping protein. We also used electron microscopy of negatively stained specimens to measure the lengths of actin filaments formed in the presence or absence of the capping protein. Although the weight-average filament length of samples with capping protein was about 25% less than controls in two different experiments, we were not convinced that the observed difference was meaningful. One problem was that the extent of the reduction in length was not proportional to the reduction in viscosity. Another was that the measured weight-average lengths of identical samples can differ by more than 25% (ref. 18).

### Effect of the capping protein on actin filament structure

Visual inspection of negatively stained actin filaments in the absence or presence of enough capping protein to inhibit the low-shear viscosity by more than 95% did not reveal any qualitative structure differences; nor was it possible to detect capping protein at the ends of the filaments. To assess possible structural differences in a more quantitative way, we prepared  $\text{Mg}^{2+}$ -paracrystals from pure actin filaments (Fig. 4a) and capping protein-actin filaments (Fig. 4c) and analysed electron micrographs of these specimens by optical diffraction (Fig. 4c,d). (Although 50 mM  $\text{MgCl}_2$  was used to make actin filament paracrystals, approximately the same amount of capping protein is bound to actin filaments in 2 mM or 50 mM  $\text{MgCl}_2$ .) In both cases we selected the 10 best diffraction patterns which showed diffraction spots to at least  $(3 \text{ nm})^{-1}$ . We measured the layer-line altitudes corresponding to the axial and structural repeats of the actin double helix (see, for an example, ref. 26). The average helix parameters for the two data sets did not differ significantly from each other: the axial repeat was  $5.5 \pm 0.1$  nm and the structural repeat was  $35.5 \pm 1$  nm in both cases. Furthermore the centre-to-centre spacing of the filaments measured directly on electron micrographs was  $6.5 \pm 0.3$  nm for both samples. Qualitatively the intensity distribution along corresponding layer lines was the same. This low-resolution structural analysis suggested that capping protein bound to actin filaments does not alter the helical structure of the filaments substantially.

### Effect of the capping protein on actin filament networks

Capping protein inhibited the low-shear viscosity of pure actin filaments (Fig. 5 inset) much more strongly than the high-shear viscosity (Fig. 2a). One microgramme of capping protein reduced the low-shear viscosity of 500  $\mu\text{g}$  actin by 90%. This inhibition of the low-shear viscosity was identical in EGTA and

in 0.1 mM  $\text{CaCl}_2$ , so the capping protein was not regulated directly by calcium. Cytochalasin B and capping protein have an additive inhibitory effect on pure actin filament low-shear viscosity; 0.1  $\mu\text{M}$  cytochalasin B reduced the viscosity by about the same amount as 0.5  $\mu\text{g ml}^{-1}$  ( $\sim 0.0003 \mu\text{M}$ ) capping protein.

Capping protein also decreased the low-shear viscosity of mixtures of actin filaments with a new 85,000-MW  $\text{Ca}^{2+}$ -sensitive gelation factor from *Acanthamoeba*<sup>27</sup> (Fig. 5) or with aldolase, a nonspecific actin cross-linker. Low concentrations of capping protein increased the concentration of cross-linker required to form a gel and concentrations of capping protein greater than 1.1  $\mu\text{g ml}^{-1}$  prevented gelation by the *Acanthamoeba* gelation factor entirely (Fig. 5).

### Interpretation

We suggest that actin filament capping protein has the following mechanism: it binds to the two actin molecules at the barbed end of actin filaments or it binds to two actin monomers at their barbed poles. In this way it might both promote nucleation, by stabilizing actin dimers, and also inhibit filament elongation by allowing growth in only the slow pointed direction. The formation of networks by pure actin filaments might be affected if the presence of capping protein at the barbed ends of filaments eliminates the cytochalasin-sensitive interactions, postulated<sup>18</sup> to be between the ends and the sides of the filaments. A second but less likely possibility for the effect of capping protein on actin filament networks is that it simply reduces the length of the filaments, as others have suggested for the action of cytochalasin B (ref. 17) and gelsolin<sup>12</sup>.

Capping protein is similar to cytochalasin B in that both block actin monomer addition at the barbed end of actin filaments<sup>18</sup> and both strongly inhibit the formation of networks by actin

**Fig. 4** Electron micrographs (a, c) and optical diffraction patterns (b, d) of actin (a, b) and capping protein-actin (c, d) paracrystals. Gel-filtered actin, 0.5  $\text{mg ml}^{-1}$ , was first polymerized for 10 min at 22 °C in 50 mM KCl, 2 mM  $\text{K}_2\text{S}_2\text{O}_8$ , 10 mM imidazole, pH 7.5, either alone or with 3  $\mu\text{g ml}^{-1}$  of capping protein.  $\text{MgCl}_2$  was then added to a concentration of 50 mM for 10 min to induce paracrystal formation. Samples diluted to 50  $\mu\text{g ml}^{-1}$  were applied to glow-discharged carbon-coated grids and stained with 0.75% uranyl formate, pH 4.3. Optical diffraction patterns were recorded from selected areas of electron micrographs of the paracrystal, typically four to six filaments wide and six to 12 structural repeats long. Scale bars, 100 nm (a, c),  $(5 \text{ nm})^{-1}$  (b, d).

**Fig. 5** Effect of filament capping protein on actin gel formation, and on the low-shear viscosity of actin filaments. Samples consisting of  $0.5 \text{ mg ml}^{-1}$  actin with 0 (●),  $0.44 \text{ μg ml}^{-1}$  (○),  $0.88 \text{ μg ml}^{-1}$  (△) or  $1.1 \text{ μg ml}^{-1}$  (□) capping protein were mixed with various concentrations of an 85,000-MW gelation protein from *Acanthamoeba*<sup>27</sup> and polymerized in capillary tubes for 10 min in 2 mM  $\text{MgCl}_2$ , 1 mM ATP, 1 mM EGTA, 10 mM imidazole, pH 7. The low-shear apparent viscosity was measured with the falling-ball device. Inset: actin alone or with several concentrations of capping protein was polymerized in capillary tubes in the conditions of Fig. 2a legend for 10 min after which the apparent viscosity was measured with the falling-ball device. Incubation for up to 40 min did not change the viscosity of actin plus  $2.2 \text{ μg ml}^{-1}$  capping protein. The electrophoretic gel illustrates the composition of a sample with  $0.5 \text{ mg ml}^{-1}$  actin with  $1.1 \text{ μg ml}^{-1}$  capping protein.

filaments<sup>17,18</sup>. In contrast, capping protein, but not cytochalasin B, promotes the formation of filament nuclei by actin monomers and inhibits annealing of actin filaments.

Both the *Acanthamoeba* capping protein and muscle  $\beta$ -actinin<sup>6</sup> inhibit polymerization rates and annealing, but they seem to be different molecules. The subunit molecular weights and Stokes' radii differ, the two proteins may be bound at opposite ends of the filament, and  $\beta$ -actinin is not a potent inhibitor of the low-shear viscosity of pure actin filaments<sup>6</sup>.

Although physiological functions cannot be proven by our purely biochemical experiments, the properties of the capping

protein molecule suggest several functions. For example, capping protein could prevent actin filament self-associations and thereby permit regulation of cytoplasmic consistency solely by variation of the extent of filament cross-linked by gelation factors<sup>14,16,27</sup>. This could be accomplished without changing the extent of actin filament polymerization or the size of the filaments. Second, the concentration of capping protein could determine the number of actin filaments in the cell. This would occur if filaments with blocked barbed ends are more stable than filaments with free barbed ends, or if spontaneous nucleation is prevented by the binding of profilin to actin monomers<sup>3</sup>. Finally, and perhaps most interestingly, capping protein could provide a link between the barbed end of actin filaments and various cellular structures to which they are attached, such as membranes.

The radio galaxy B2 1141+37 is remarkable for both its radio and optical properties. The radio source has a double structure for which the ratio of the separation between the components to their dimension is exceptionally large. Moreover, our recent measurement of the redshift gives  $z = 0.115$  giving a separation between the components of 1.0 Mpc. This makes 1141+37 one of the largest radio structures known. The optical identification which has been proposed is a tight chain of galaxies which are

probably gravitationally bound. If this is the case, the radio galaxy must have some precession and/or rotation motion around the centre of mass of the group with important consequences on the structure and evolution of the radio source. We report here on the redshift measurement and on some VLA observations at 4.9 GHz.

The radio source is formed by the two sources of the Bologna Catalogue B2 1141+37 A and B, and is also 4C37.42. It is one of the objects in the sample of radio galaxies which was analysed by Meier *et al.*<sup>1</sup> to obtain the luminosity function of radio galaxies, and it is the only object in that sample for which the redshift was not measured.

The map<sup>2</sup> of B2 1141+37 obtained at 1,415 MHz with the Westerbork Synthesis Radio Telescope shows two intense components of nearly equal intensity separated by 264 arc s and with dimensions of  $65 \times (<30)$  arc s for the NE component and  $20 \times (<30)$  arc s for the SW component. No third component was detected along the line joining the two bright components. Polarization of 4% and 3% at 1,415 MHz has been detected in the SW and NE components respectively<sup>7</sup>.

The radio source was re-observed at 4,900 MHz with the VLA in August 1978 during observations of the central sources

Fig. 1 Radio lobes observed at 1,415 MHz (ref. 2) on a print of the Blue Sky Survey photograph. Scale bar, 100 arc s.

of several radio galaxies from the Bologna Catalogue<sup>3</sup>. Five integrations of 5 min were done, but after removing the scans affected by phase shifts due to stormy weather, the effective integration time was 17 min. The map obtained with a grid of  $3 \times 3$  arc s and a gaussian taper falling to 50% at 2.5 km in the  $(u, v)$  plane shows two radio lobes with maxima at the positions indicated in Table 1 and exactly coinciding with the maxima in the 1,415 MHz map<sup>2</sup>. The intensities of the NE and SW lobes at

4,900 MHz are 0.23 and 0.18 Jy, respectively. These values are both  $\sim 1.5$  times smaller than the values obtained by extrapolating to 4,900 MHz the spectrum defined by the flux density at 408 and 1,415 MHz,  $f_\nu \propto \nu^{-0.84}$ , of the two radio lobes. This suggests that some flux is missing in the 4,900-MHz map, and this is probably caused by the fact that the shortest baseline spacing of the VLA observations was 480 m. No central source brighter than 0.03 Jy has been detected at the location of the optical identification.

A tight chain of four galaxies located very close to the mid-point between the two radio components has been proposed as the optical identification<sup>2</sup>. We have recently measured the redshifts of the two brightest galaxies in the chain, galaxies 1 and 2 in Fig. 1, with the image intensified dissector scanner of the 4 m telescope at Kitt Peak National Observatory. Galaxy 1 shows the *K*, *H*, and *G* features and the [O II]  $\lambda 3,727$  emission line at a redshift  $z = 0.1145 \pm 0.0005$ . The scan of galaxy 2 shows the *K* and *H* lines at  $z = 0.1155 \pm 0.005$ . Galaxy 1, being the brightest and having a spectrum with at least one emission line, is likely to be the radio galaxy among the four members of the chain. Taking  $H = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ , the distance to the radio source is 687 Mpc and 1 arc s corresponds to 3.3 kpc. The distance between the edges of the two radio lobes is, therefore, 1.0 Mpc making it one of the largest radio sources known. The minimum energy in the radio lobes, the energy density, and the equipartition magnetic field have been calculated following the procedure of McDonald *et al.*<sup>4</sup> and making no allowance for the presence of high energy protons. The calculations are based on the flux density at 604 MHz which is calculated by interpolating the radio spectrum defined by the flux density at 408 and 1,415 MHz,  $f_\nu \propto \nu^{-0.84}$ . The values corresponding to the NE component are listed in Table 2 together with the values of the same parameters for the E component of 3C236 (ref. 5) and for the outer compact component in the W lobe of Cyg A (component 'D' in ref. 6). For Cyg A we have calculated the energy from the flux measured<sup>6</sup> at 5 GHz extrapolated to 604 MHz with a power law spectrum  $f_\nu \propto \nu^{-1}$  and assuming that this flux comes from a region which has the same dimensions as

those measured<sup>6</sup> at 5 GHz. Comparison of the values of the energy density in the radio lobes of 1141+37 and in the outer compact component of Cygnus A indicates that 1141+37 is in a more relaxed state.

A full synthesis map of 1141+37 would be particularly interesting for several reasons. First, there are very few radio galaxies with comparable dimensions. Second, the inner radio structure should contain information related to the motion of the parent radio galaxy in its group. The closeness in redshifts of galaxy 1 and 2 and the tight group which they form in the plane of the sky with the other two smaller galaxies suggest that this is a gravitationally bound group. If this is the case, the radio galaxy, probably galaxy 1, has some precession motion and/or rotation motion around the centre of mass of the group. The direction of the beam along which the particles have been ejected must, therefore, have recently undergone some changes influencing the shape and the evolution of the radio structure between the outer lobes and the parent radio galaxy.

## Two-dimensional model calculations of stratospheric HCl and ClO

C. Miller\*, J. M. Steed†, D. L. Filkin\* & J. P. Jesson†

\* Engineering Department and † Central Research and Developments, El du Pont de Nemours and Company, Experimental Station, Wilmington, Delaware 19898

Most previous attempts to estimate the effects of atmospheric contaminants on stratospheric ozone have involved one-dimensional models of the troposphere and stratosphere. Estimates of the distribution of HCl and ClO with height have, however, failed to match the measured concentration profiles<sup>1</sup>. Hence, there has been much interest in the development of two-dimensional atmospheric models which, by including variations with latitude and seasonal effects, might remove these discrepancies. We have developed such a two-dimensional model which incorporates the refinements of the most advanced one-dimensional models; we now report that, contrary to expectation, the calculated profiles of HCl and ClO are insignificantly different from those of comparable one-dimensional models.

Our model includes 30 active chemical species ( $\text{H}_2\text{O}$ ,  $\text{CH}_4$ ,  $\text{H}_2$ ,  $\text{CO}$ ,  $\text{CH}_2\text{O}$ ,  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{HNO}_3$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}_3$ ,  $\text{N}_2\text{O}_5$ ,  $\text{HO}_2\text{NO}_2$ ,  $\text{N}$ ,  $\text{HCl}$ ,  $\text{ClO}$ ,  $\text{Cl}$ ,  $\text{ClONO}_2$ ,  $\text{HOCl}$ ,  $\text{O}(^3\text{P})$ ,  $\text{O}(^1\text{D})$ ,  $\text{O}_3$ ,  $\text{H}_2\text{O}_2$ ,  $\text{OH}$ ,  $\text{HO}_2$ ,  $\text{H}$ ,  $\text{CFCl}_3$ ,  $\text{CF}_2\text{Cl}_2$ ,  $\text{CCl}_4$ ,  $\text{CH}_3\text{Cl}$ ,  $\text{CH}_3\text{CCl}_3$ ) and all chemical reactions and reaction rates from the current NASA kinetics documentation<sup>2</sup> applicable to these species, except that a single pair of reactions in the model methane oxidation sequence is assumed to describe the instantaneous fate of  $\text{CH}_3$  and  $\text{HCO}$  radicals:

More recent reaction rates for  $\text{OH} + \text{H}_2\text{O}_2$  (refs 3, 4) and  $\text{HO}_2\text{NO}_2$  photolysis<sup>5</sup> have, however, been used.

In this model, the transport of all chemical species is calculated separately, except in the odd-oxygen family ( $\text{O}_3$ ,  $\text{O}(^3\text{P})$  and  $\text{O}(^1\text{D})$ ) and H and N atoms (the latter two are assumed to be in photochemical equilibrium). The domain of the model is from pole to pole and from 0 to 55 km. Solar declination angle, temperature field, number density field and transport coefficients are specified for quarter-year intervals to allow for seasonal variations. The treatment of diurnal effects and the approach used for Rayleigh scattering of solar radiation are described by Miller *et al.*<sup>6</sup>. Rainout of soluble species occurs below 10 km with a 5-day time constant.

Mean meridional circulation is parameterized using the advective circulation field of Murgatroyd and Singleton<sup>7</sup>, with a scale factor of 0.4. Dunkerton<sup>8</sup>, Matsuno<sup>9</sup> and Schoeberl (personal communication) have indicated that, with downward scaling to account for improvements in calculated stratospheric heating rates<sup>10</sup>, this field should reasonably approximate the so-called lagrangian mean motion. The lagrangian mean, which resembles a simple Brewer–Dobson<sup>11,12</sup> cell, combines the zonal eulerian mean motion with a meridional advective contribution arising from planetary waves<sup>9</sup>. This is the first attempt in a complete two-dimensional chemical model to simulate directly the effects of the lagrangian mean circulation.

The eddy diffusion parameterization is basically that of Luther<sup>13</sup>, with the latitudinal coefficient  $K_{yy}$  adjusted below 10 km to give a realistic interhemispheric mixing time of ~14 months (ref. 14). This adjustment produces negligible changes in calculated stratospheric profiles of HCl and ClO. The vertical eddy diffusion coefficient  $K_{zz}$  is the most uncertain aspect of Luther's parameterization, and has been replaced by that of Hunten<sup>15</sup> for all seasons throughout the model stratosphere.

Spatial derivatives for transport are approximated by a second-order finite difference representation that automatically conserves mass. Grid resolution is 5 km vertically and 0.2 in the sine of latitude. Fluxes across upper (55 km) and polar boundaries are set to zero for all species. Ground-level species mixing ratios and fluxes are provided as a function of latitude.

The time-dependent integration uses an implicit finite difference formula, second order in the time increment with respect to transport, and first order for chemistry. At each integration step, the finite difference formula is solved by a Newton–Raphson iteration until convergence is achieved. The calculations are performed on a CRAY 1 computer.

Figure 1 compares the calculated latitudinal variations of the  $\text{N}_2\text{O}$  volume mixing ratio with a selection of the available measurements<sup>16–21</sup>. Agreement is excellent in all latitude bands examined. Results for other upward-moving species such as  $\text{CFCl}_3$ ,  $\text{CF}_2\text{Cl}_2$  and  $\text{CH}_4$  are similar. The vertical gradient in  $\text{N}_2\text{O}$  mixing ratio is steeper towards the poles than towards the equator, indicating that tropical upwelling associated with the Hadley cell is reproduced qualitatively by the prescribed lagrangian circulation.

Model results for column ozone are consistent with measurements by Wilcox *et al.*<sup>22</sup> at all latitudes, as shown by the mid-spring comparison in Fig. 2. Column  $\text{HNO}_3$  is considerably improved relative to previous two-dimensional simulations<sup>23,24</sup>, which typically exceed the measurements of Murcray *et al.*<sup>25</sup> by factors of 2–3 at latitudes below 30°. Present calculations fall within the data range in this region, an improvement largely attributable to the use of a lagrangian mean velocity field.

The calculated daytime average vertical profiles for HCl and ClO in May 1977 vary considerably with latitude (Fig. 3). Short-term temporal and local variations might be expected in regions of large spatial gradients. Where the spatial gradient is high for HCl, for example, local variability might be expected below ~30 km, possibly accounting for the observed 'dips' in measured HCl profiles. The seasonal variations suggested by these profiles (for example, 30°N versus 30°S) are, to a first approximation, chemical consequences of changes in the solar

Fig. 1 Calculated vertical profiles of the  $N_2O$  volume mixing ratio for several latitudes are compared with a selection of measurements (refs 16–21).  $\circ$ , Golden *et al.* (1979);  $\blacksquare$ , NASA Ames Group: Vetter *et al.* (1978), Tyson *et al.* (1978); ----, Fabian *et al.* (1979);  $\square$ , Ehhalt *et al.* (1975);  $\triangle$ , Farmer *et al.* (1980);  $\blacksquare$ , model range over a year.

declination angle rather than of total transport of CIX ( $= HCl + ClO + ClONO_2 + Cl + HOCl$ ). Below 20 km, seasonal variability is small because  $HCl \approx CIX$ , but latitudinal variations are quite large.

The range of model-calculated profiles during 1977 for HCl at  $30^\circ N$  latitude (for  $\sim 1.8$  p.p.b. (parts per  $10^9$ ) total CIX) is plotted in Fig. 4 together with spectroscopic experimental profiles (from refs 26–30 and Zander, personal communication, 1979), which were obtained between late 1975 and late 1978 at a comparable latitude ( $\sim 32^\circ N$ ). The *in situ* base-coated filter measurements of Lazrus *et al.*<sup>31</sup> are believed to include  $ClONO_2$  and  $HOCl$ , in addition to HCl, and are therefore not included in Fig. 4. Also, these measurements lie consistently below not only the sum of calculated acidic chloride species, but also virtually all

spectroscopically measured HCl profiles in the region above 28 km.

The calculated HCl profiles in Fig. 4 fall within the envelope of the measurements, exhibiting a qualitatively similar trend of monotonically increasing mixing ratio with increasing altitude. Some measurements also indicate dips that may be due to local variability. The average slope of the calculated profile differs quantitatively from the measurements, with the calculated mixing ratios below 25 km falling at the high end of the measurement envelope, and the values above 25 km deviating towards the low end. These differences are similar to deviations in slope which are observed for HCl in one-dimensional model calculations<sup>32</sup>.

Figure 5 plots the range of two-dimensional model calculations for daytime average ClO over 1977 at  $30^\circ N$  latitude and the measurements of Anderson *et al.*<sup>33</sup> by *in situ* resonance fluorescence and Menzies<sup>34</sup> by laser heterodyne radiometer. If the 28 July 1976 and 14 July 1977 ClO profiles of Anderson are excluded as being unrepresentative of the 'normal' range for that species, then, according to the figure, the model significantly overestimates the abundance of ClO between 25 and 30 km. This overestimation of lower stratospheric ClO is an important problem<sup>35</sup>, because a major part of the calculated ozone depletion by chlorofluorocarbons occurs below  $\sim 30$  km in the current chemical scheme. Furthermore, it suggests that there may be a problem with CIX partitioning in this altitude region, because ClO represents only a small fraction of total CIX and because calculated HCl is in reasonable agreement with the spectroscopic measurements between 25 and 30 km.

The discrepancy between the calculated and observed ClO profiles in the lower stratosphere is also a feature of one-dimensional modelling calculations. Relative to the one-dimensional case, the present two-dimensional result represents only a minor improvement in agreement between experiment and theory<sup>32</sup>. Although the pioneering two-dimensional modelling results of Pyle<sup>36</sup> have been interpreted as suggesting that the discrepancy would be removed in other two-dimensional simulations<sup>1</sup>, this improvement is not found in the present calculation. Other multi-dimensional model results reported by the UK Department of the Environment corroborate this conclusion<sup>37</sup>. The improved agreement in the calculations of Pyle is related partly to his lower calculated abundance of total CIX in the lower stratosphere and partly to his use of a slower rate for the reaction  $HO_2 + NO$ .

Fig. 2 Model-calculated column ozone as a function of latitude during Northern Hemisphere spring (solid line) is compared with measurements by Wilcox *et al.*<sup>22</sup> ( $\square$ ).

**Fig. 3** Calculated vertical mixing ratio profiles of HCl and ClO (daytime average) for several latitudes in May 1977.

**Fig. 4** The range of model-calculated HCl profiles during 1977 at 30°N (■) plotted together with a selection of experimental measurements; a, ref. 30; b, ref. 27; c, ref. 28; d, ref. 29; e, ref. 26; f, Zander, personal communication; made in the same year.

**Fig. 5** The range of model-calculated ClO profiles (daytime average) during 1977 at 30°N (■) is plotted together with the *in situ* resonance fluorescence profiles of Anderson *et al.*<sup>33</sup> and the laser heterodyne radiometer measurement of Menzies<sup>34</sup>.

In the 30–40-km region the agreement between calculated and measured HCl values could be improved considerably by an increase in the maximum ClX mixing ratio from ~1.8 to ~2.5 p.p.b. for 1977. However, such an adjustment would also increase the calculated abundances of both HCl and ClO at altitudes below 30 km, and would therefore produce larger deviations from experiment in the lower stratosphere, given the current chemistry. Furthermore, a mixing ratio of ~2.5 p.p.b. ClX for 1977 would be difficult to reconcile with currently identified source strengths.

Consideration of the behaviour of both HCl and ClO in Figs 4 and 5 suggests that the calculated ratio of ClO/HCl exceeds measurements at all altitudes below 40 km, with the largest deviations occurring in the lower stratosphere. This implies that problems may exist in partitioning of ClX, not merely in the 25–30-km region, but also at altitudes up to 40 km.

The present ClX profiles from a two-dimensional chemical model with advanced treatment of both chemistry and transport indicate that, at 30°N, the comparison with measurements is similar to that obtained with one-dimensional models. In particular, the overestimation of ClO in the lower stratosphere, present in both one- and two-dimensional calculations, is directly related to the large ozone reductions calculated in that region for the fluorocarbon perturbation. As this is also the region where both transport and chemistry are most uncertain, these discrepancies may be reconciled by future revisions to accepted input parameters. At present, discrepancies in total ClX and in partitioning among ClX species imply that the problems are not unique to one-dimensional models and that a reasonable treatment of meridional transport and chemistry does not remove the current disagreements.

## Large rain drops in the bright band

Edward E. Altshuler

Rome Air Development Center, Electromagnetic Sciences Division, Hanscom AFB, Bedford, Massachusetts 01731

It has recently been suggested<sup>1–3</sup>, based on dual-polarized radar measurements, that in the bright-band region, melting snow exhibits the characteristics of rain drops having very large effective drop diameters. It is postulated that snow flakes falling below the 0 °C isotherm melt slowly with small water droplets first forming on the outer edges of the flakes; as the snow continues to melt water forms on the surface of the flake, thus it takes on the behaviour of a large rain/ice drop; in the final stages of melting the particles start to collapse into smaller drops. Here another technique for inferring rain-drop sizes<sup>4</sup> is described which produces results which, being consistent with those above, support the bright-band model.

Based on calculations by Medhurst<sup>5</sup>, rain attenuation can be shown to be a strong function of frequency and drop diameter. In Fig. 1, the ratio of the attenuation at 35 GHz to that at 15 GHz is plotted as a function of drop diameter and it is seen that for small drops, the ratio of the attenuations may be very large but as the drop size increases, the ratio decreases. Although Medhurst's calculations assume hypothetical distributions of rain in that they are for spherical drops all having the same size and temperature, his results are of qualitative value and enable the average drop diameter of the rain to be estimated from measurements of attenuation at two widely separated frequencies. Unfortunately, with the radiometric technique for measuring attenuation, it is not possible to obtain attenuation as a function of distance along the path directly, as

Fig. 1 Ratios of 35-GHz to 15-GHz attenuations as a function of rain-drop diameter and rain rate.

Fig. 2 Ratios of measured 35-GHz to 15-GHz attenuations as a function of 15-GHz attenuation.

can be done with radar. Drop size distributions of rain have been measured at ground level<sup>6</sup> and a strong correlation between rain rate and the average drop size has been shown; light rain typically consists of small drops of 1- or 2-mm diameter, whereas heavy rain has larger-diameter drops of 3–5 mm. The attenuations corresponding to these drop size distributions can be calculated so the attenuation ratio can also be expressed as a function of rain rate as shown in Fig. 1. Note that the attenuation ratios of ground-level rain would be expected to fall in the range 4–7.

Slant-path attenuation measurements at frequencies of 15 and 35 GHz were conducted in the Boston area, during eight rainstorms with various rain-fall intensities, using the Sun as a source<sup>4</sup>. A dual-frequency radiometer mounted in an 8.8-m paraboloidal antenna was the detector. Antenna beamwidths were approximately 9 and 4 arc min respectively and the centre of the Sun was tracked with an accuracy of at least 0.5 arc min. Over 10,000 simultaneous measurements of attenuations at 15 and 35 GHz were recorded during a year. The ratios of these attenuations are plotted against the 15-GHz attenuations in Fig. 2. Data points corresponding to 15-GHz attenuations below 0.5 dB were not included because they were probably too low to be due to rain and also the measurement accuracy at these low attenuations is poor. If the rain-drop size distributions along the slant path were similar to those which have been measured on the ground, then one would expect the attenuation ratios to be of the order of 6 or 7 for low rain rates (low 15-GHz attenuations) and decrease to about 4 or 5 for the higher rain rates which would correspond to higher 15-GHz attenuations. Of the points which are plotted, the bulk of these have ratios between 2 and 4 and occur for low 15-GHz attenuations. Therefore, these results are not consistent with ground-level rain-drop size distributions but suggest instead that somewhere along the slant path there is a significant contribution to the attenuation which results from precipitation, with characteristics of rain drops having very large effective drop diameters, as noted in the drop-diameter curve of Fig. 1. Because most of the rain along the path occurs below the bright band, the attenuation contribution from the bright band would be expected to be relatively small. Yet, the fact that the attenuation ratios are so low means that there must be very large drops in the bright-band region and therefore drop diameters of the order of 10–20 mm, as suggested by Humphries and Barge<sup>2</sup>, are certainly possible.

Note that it may be advantageous to conduct both dual-frequency attenuation and dual-polarized reflectivity measurements to differentiate between rain and ice. The

attenuation measurement easily distinguishes rain from ice particles as losses due to ice are much smaller; this is not always the case with radar because both ice and rain have high reflectivity. In addition, if the attenuation through the absorbing medium is known, the radar can be more accurately calibrated.

I thank Dr Robert K. Crane for helpful discussions.

## Proton mobility in ice

Marinus Kunst & John M. Warman

Interuniversitair Reactor Instituut, Mekelweg 15, 2629 JB Delft, The Netherlands

Ice is frequently taken as a model when factors controlling proton transport in hydrogen-bonded molecular networks are discussed. Such discussions have increased with the acknowledgement that proton transfer across cell membranes may play a significant part in energy conversion and storage in biological systems<sup>1–4</sup> and that this transfer may involve hydrogen-bonded chains spanning the membrane<sup>5,6</sup>. However, there is still much uncertainty about the basic mode of proton displacement and the external factors which effect bulk proton transport in ice itself. We present here results of a microwave conductivity pulse radiolysis technique which has been used to determine the mobility of bare protons in ice, and thus reduce some of the uncertainty over proton mobility.

The displacement of protons through a Grotthuss-type mechanism can only occur if a subsidiary mechanism is available to wipe out the polarization field produced by dipole reversals which accompany proton jumps. This led Bjerrum to introduce *L* and *D* orientation defects. For a sufficiently high concentration of Bjerrum defects, resistance to proton motion due to bulk polarization should become negligible. In these conditions, therefore, the net drift mobility of protons in an applied field,  $\mu(H^+)_{\infty}$ , should be equal to the microscopic or virtual mobility,

$M(H^+)$ . The latter parameter is of considerable interest because it reflects the basic mode of proton displacement.

However, the situation may be complicated<sup>7,8</sup> by the formation of immobile complexes between protons and the net negatively charged  $L$  defects.

The net drift mobility, even for high concentrations of orientational defects, will, therefore, give only a lower limit to  $M(H^+)$ :

$$\mu(H^+)_{\infty} = M(H^+) \frac{[H_3O^+]}{[H_3O^+] + [H_3O^+L]} \quad (2)$$

The presently accepted values of the proton mobility in ice at close to the melting point are considerably lower than the estimate of  $7.5 \times 10^{-2} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  by Eigen *et al.*<sup>9</sup> and tend to lie within the range  $(0.5-5) \times 10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  (ref. 11). The temperature dependence of the mobility is not accurately known. There are indications of increasing mobility with decreasing temperature<sup>12,13,15</sup>. However, zero activation energy for the mobility is frequently assumed even in recent theoretical models of the dielectric properties of ice<sup>17</sup>.

We have studied the change in conductivity which results from pulsed ionization of ice using 3-MeV electrons from a Van de Graaff accelerator. The present results were obtained in the temperature range  $-5$  to  $-30^\circ \text{C}$  using 50-ns long pulses with a total dose per pulse of  $\sim 1 \text{ krad}$  ( $\sim 5 \times 10^{16} \text{ eV cm}^{-3}$ ). The concentration of ions formed was  $\leq 1 \times 10^{-6} \text{ M}$ . The experimental set-up and background to the microwave conductivity technique used have been described elsewhere<sup>18,19</sup>. Figure 1 shows the conductivity transient observed in  $\text{H}_2\text{O}$  ice at  $-7^\circ \text{C}$ .

The results can be discussed in terms of the main ionic processes occurring on irradiation:

The highly mobile ( $\sim 10 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ) conduction electrons,  $e^-$ , have a mean lifetime towards localization at pre-existing lattice-defect sites,  $T$ , of 100 ps at  $-5^\circ \text{C}$  (ref. 18). This process is responsible for the initial, very rapid decay of the conductivity on termination of the pulse. Further relaxation to give the deeply trapped ( $\lambda_{\text{max}} = 680 \text{ nm}$ ) (refs 20-22), 'solvated' state of the electron,  $e_{\text{sol}}^-$ , occurs with a mean time of 400 ps (C. D. Jonah and our unpublished results). The relatively slowly decaying

**Fig. 1** Transient digitizer trace of the change in conductivity of  $\text{H}_2\text{O}$  ice at  $-7^\circ \text{C}$  which results on pulsed ionization using a 50-ns pulse of 3-MeV electrons (beam charge 60 nC). The maximum signal height corresponds to a conductivity of  $\sim 2 \times 10^{-4} \Omega^{-1} \text{ m}^{-1}$ . The signal during the pulse is due mainly to the steady-state concentration of highly mobile conduction electrons which undergo trapping in  $\sim 0.1 \text{ ns}$  at this temperature. This electron component is seen to decay very rapidly on termination of the pulse but an appreciable, relatively slowly decaying conductivity transient remains. This transient is attributed to proton conduction.

conductivity transient apparent in Fig. 1 cannot therefore be attributed to the migration of weakly localized electrons through the conduction band or by trap-to-trap hopping.

Because the formation of  $\text{H}_3\text{O}^+$  through the proton-transfer reaction (5) is expected to take place within a few O-H vibrations<sup>23</sup> or  $\text{H}_2\text{O}^+$  displacements<sup>24</sup> and should certainly be complete well within the nanosecond time scale of the present experiments, we conclude that the slowly decaying conductivity is due to mobile protons.

The present measurements were carried out using microwaves, so that effects on the proton mobility due to polarization of the medium can be neglected. The initial after-pulse conductivity should then be proportional to the product of the proton yield and the virtual mobility  $M(H^+)$ . Using the known dosimetry, the parameter  $G(H^+)M(H^+)$ , where  $G(H^+)$  is the yield in ions per 100 eV absorbed, can be determined from the conductivity signal after correction for a certain amount of decay during the pulse. At  $-5^\circ \text{C}$ , the yield times mobility product is determined to be  $6.4 \times 10^{-3}$  and  $2.4 \times 10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1} (100 \text{ eV})^{-1}$  for  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$  ice respectively.

From optical absorption pulse radiolysis studies<sup>20,22</sup>, the yield of solvated electrons is found to be  $1.0 \pm 0.2 (100 \text{ eV})^{-1}$  for  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$  ice at  $-5^\circ \text{C}$ . Taking the yield of protons to be equal to the yield of solvated electrons results in estimates of virtual mobilities of  $\text{H}_3\text{O}^+$  and  $\text{D}_3\text{O}^+$  of  $6.4 \times 10^{-3}$  and  $2.4 \times 10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ . As expected on the basis of the initial discussion, the value of  $M(H^+)$  lies above the range of drift-mobility values determined from low-frequency dielectric measurements on ice at equilibrium.

Of considerable importance to theoretical models of proton transport is the temperature dependence of  $M(H^+)$ . For both  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$ , the yield times mobility product is found to remain almost unchanged between  $-5$  and  $-30^\circ \text{C}$  with a slight,  $\sim 10\%$ , increase being indicated for  $\text{H}_2\text{O}$ . Over this same temperature range, the yield of ions formed, as measured by the solvated electron absorption, decreases considerably<sup>20-22,25</sup>. A pronounced increase in the virtual mobility with decreasing temperature is therefore indicated.

The electron yield at  $-30^\circ \text{C}$  is quite sensitive to the conditions of pulse width and total dose used<sup>20,26</sup>. It can be concluded, however, that the ion yield is at least a factor of 2 lower at the lower temperature. It may then be concluded that the virtual mobility has a negative activation energy of at least 0.15 eV which corresponds to an inverse sixth-power dependence on temperature in the present range.

Such a large negative energy of activation is incompatible with simple theoretical models involving hopping or tunnelling of protons between isoenergetic states separated by a potential energy barrier. A more complex approach, in which interaction between the charged particle as a whole and lattice vibrations is taken into account, has been shown by Gosar and Pintar<sup>27</sup> to predict a mobility which sharply decreases with increasing temperature. Fischer and Hofacker<sup>28</sup> pointed out that proton conduction can be treated in an analogous way to that used for narrow-band polaron transport. In the low-temperature regime, the narrow-band polaron mobility is given by<sup>29</sup>

$$\mu = \frac{ea^2}{kT} \pi^{1/2} \nu_0 F(T)^{1/2} \exp[-F(T)] \quad (6)$$

with

$$F(T) = \frac{2W_p}{h\nu_0} \text{cosech} \frac{h\nu_0}{2kT} \quad (7)$$

In equations (6) and (7),  $a$  is the intermolecular distance ( $2.76 \text{ \AA}$  in the present case),  $\nu_0$  is the unperturbed natural frequency of the vibrational mode interacting with the charge, and  $W_p$ , the polaron binding energy, is the potential energy gained by the charge due to lattice distortion.

In the case of ice, strong interactions of  $\text{H}_3\text{O}^+$  with both the oxygen-oxygen lattice mode,  $h\nu_0 = 0.025 \text{ eV}$ , and the restricted rotation or libration mode,  $h\nu_0 = 0.1 \text{ eV}$ , have been suggested<sup>28</sup>.

The measured value of  $M(H^+)$  of  $6.4 \times 10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  at  $-5^\circ \text{C}$  is obtained using equation (6) with  $W_p/h\nu_0 = 1.72$  or  $16.6$  for  $h\nu_0 = 0.025$  or  $0.1 \text{ eV}$  respectively. Using the same combinations of parameters, an increase in mobility by factors of 1.9 and 4.6 respectively would be predicted on decreasing the temperature to  $-30^\circ \text{C}$ . The predicted effect of temperature is of the same magnitude as found. However, because of the large uncertainty in the value of the ion yield at  $-30^\circ \text{C}$ , the temperature dependence alone cannot be used to specify which lattice interaction predominates. The isotope effect of a factor of 2.7 in the mobility, however, favours the lower energy mode, if the polaron binding energy is assumed to be the same for both isotopes. Thus the decrease in frequency of  $\sim 5\%$  for the oxygen-oxygen vibration corresponds to a decrease in mobility using equation (6) by a factor of 1.9. For the librational mode the shift in frequency is  $\sim 30\%$  (ref. 30), which would result in the prediction of a mobility a factor of almost  $10^4$  lower for the heavier isotope.

An interesting aspect of the general narrow-band polaron theory is the prediction of a sharp changeover to a thermally activated hopping motion at higher temperatures<sup>29,31,32</sup> with, however, an activation energy which decreases with increasing temperature. At sufficiently elevated temperatures, a maximum in the mobility is predicted<sup>29</sup>. This behaviour is descriptive of the temperature dependence of the excess mobility of protons in liquid  $\text{H}_2\text{O}$  (refs 33, 34).

The proton conductivity signal is found to decay over a period of a few hundred nanoseconds to a much lower level (10–20% of the initial signal) which then further decreases over many microseconds. The slow decay occurs on the same time scale as observed for the solvated electron disappearance in optical studies<sup>22</sup> for similar dose conditions and is therefore ascribed to the recombination reaction

The initial relatively rapid decay is attributed to a pseudo first-order reaction of bare protons with  $L$  defects, present at a concentration of  $\sim 10^{-5} \text{ M}$  (ref. 35) resulting eventually in a considerably lower equilibrium concentration of  $\text{H}_3\text{O}^+$ .

The ratio between the initial conductivity and the low-level, slowly decaying component is equal to the concentration ratio  $([\text{H}_3\text{O}^+] + [\text{H}_3\text{O}^+L])/[\text{H}_3\text{O}^+]$  at equilibrium. The ratios found at  $-5^\circ \text{C}$  are 8 and 10 for  $\text{H}_2\text{O}$  and  $\text{D}_2\text{O}$  respectively. Combining these ratios with the above values of the virtual mobilities gives the effective drift mobilities  $\mu(H^+)_{\infty} = 8 \times 10^{-4}$  and  $\mu(D^+)_{\infty} = 2 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ . The value of  $\mu(H^+)_{\infty}$  lies close to the lower limit of the range of mobility values derived from low-frequency dielectric measurements. Drift mobility estimates larger than  $\mu(H^+)_{\infty}$  could be due to perturbation of equilibrium (1) by excessive applied fields.

In summary, using a nanosecond pulse radiolysis microwave conductivity technique, the virtual mobility of protons in  $\text{H}_2\text{O}$  ice has been determined to be  $6.4 \times 10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ , and of deuterons in  $\text{D}_2\text{O}$  ice to be  $2.4 \times 10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  at  $-5^\circ \text{C}$ . These values increase by a factor of at least 2 on decreasing the temperature to  $-30^\circ \text{C}$ . This corresponds to a negative activation energy of at least  $0.15 \text{ eV}$ . The narrow-band polaron theory is capable of describing the data with the main charge interaction apparently involving the  $200 \text{ cm}^{-1}$  oxygen-oxygen lattice vibration. Temporary complexing of protons with  $L$  defects reaches equilibrium within a few hundred nanoseconds and results in effective drift mobilities of  $8 \times 10^{-4}$  and  $2 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  for  $\text{H}_3\text{O}^+$  in  $\text{H}_2\text{O}$  and  $\text{D}_3\text{O}^+$  in  $\text{D}_2\text{O}$  respectively at  $-5^\circ \text{C}$ .

Kinetic and thermodynamic parameters will be discussed elsewhere.

## Evidence against a crystal instability in melting

R. M. J. Cotterill & J. U. Madsen

Department of Structural Properties of Materials, The Technical University of Denmark, Building 307, DK-2800 Lyngby, Denmark

Since Born's original suggestion<sup>1</sup>, melting has frequently been attributed to a crystal instability although its one-phase approach has been objected to. Using a molecular dynamics computation of the behaviour of a 336-atom Lennard-Jones system, and exploiting the inherent limitations on model size and simulation time, we have found a crystal-liquid instability. It falls outside the density interval for thermodynamic melting, however, and we conclude that it is not true melting. We have also discovered an isothermal liquid-glass transition on compressing the liquid, and this occurs at a density within the transition interval. The results reported here are consistent with the first-order nature of melting and provide new insight into the difference between the crystalline and liquid states.

A sufficiently large system, given enough time, would melt by traversing the two-phase region, whereas a limited model like ours can explore nonequilibrium states. A similar model has, for example, probed the van der Waals loop of the liquid-gas transition (S. Toxvaerd, personal communication). Our three-dimensional system, with periodic boundaries, has been investigated at various densities in the melting region. The studies extended those of Damgaard Kristensen<sup>2</sup>, using the same model and the same reduced units. (The diatomic Lennard-Jones interaction energy is  $V_{LJ} = \epsilon((r_0/r)^{12} - 2(r_0/r)^6)$ ; reduced units are used throughout—lengths in units of  $r_0$ , energies  $\epsilon$ , temperatures  $\epsilon/k_B$ , densities  $\rho/\rho_0^*$ , pressures  $\epsilon/r_0^3$ .) An equation of state was first established for the face-centred cubic (f.c.c.) phase for densities 1.20–1.35 and temperatures 0.5–1.0. All state points were derived on the basis of 5,000 computational time steps, each of duration 0.003 in reduced units ( $2 \times 10^{-14} \text{ s}$ ). The zero-pressure and higher-pressure isobars all displayed divergence of the isobaric volume expansion coefficient for the (metastable) f.c.c. phase, as implied by the vertical tangent of each isobar, and this defined an unequivocal

**Fig. 1** The  $T = 0.77$  isotherms of crystal, liquid and glass with the experimental points indicated. The arrow indicates the position of the crystal instability, and the intersection of the extrapolated lines locates a formal glass transition density. A–F, The expansion and compression sequence of states described in Fig. 2.

thermodynamic stability limit<sup>3</sup>; however, for the small system investigated the limit can be bypassed slightly<sup>4</sup>. A typical isotherm for  $T = 0.77$ , starting with the f.c.c. state is shown in Fig. 1. A discontinuous jump in pressure is observed at a density of 1.22. (All isotherms exhibited discontinuities which were sharp within computational limits, the discontinuity density increasing with temperature.) Beyond the discontinuity, pressure again decreased with density. The isotherm was retraced if the density was then increased, but the pressure rose continuously and passed the discontinuity with no detectable change of slope. A change in slope was encountered, however, at a higher density, as shown in Fig. 1.

The pair distribution function,  $g(r)$ , and a bond-angle distribution function,  $f(\theta)$ , defined elsewhere<sup>5</sup>, were monitored for all the states indicated in Fig. 1. These functions are shown in Fig. 2. For  $g(r)$ , the  $\sqrt{2}$ -peak, a signature of the f.c.c. structure, a remnant flat portion at B, was totally absent at C. States C to F had liquid-like  $g(r)$ , with the suggestion of second-peak splitting present at F. The well defined second-peak splitting reported for hard sphere model glasses<sup>6</sup> was smeared out, presumably by

thermal vibrations. We conclude that the discontinuity is associated with a crystal–liquid transition and that a liquid–glass transition is obtained by compressing the liquid. The glass transition density increased slightly with increasing pressure and temperature relative to the zero-pressure transition density located by Damgaard Kristensen<sup>2</sup>. For  $f(\theta)$ , there were more pronounced differences between B and C: the  $90^\circ$  peak and the  $150^\circ$  depression, still both seen in B, were absent in C. Because the  $90^\circ$  bond angle is a characteristic of the f.c.c. structure, this supports our conclusion that the discontinuity corresponds to crystal breakdown. Here too, E and F differed markedly: the  $60^\circ$  and  $110$ – $120^\circ$  peaks were much sharper in F, and the shoulder at  $150^\circ$  more pronounced, both features are glassy-state characteristics<sup>7</sup>.

Using a Monte-Carlo technique to locate free energy equality, and hence melting pressures for given melting temperatures, Hansen and Verlet<sup>8</sup> derived the fluid and solid densities at melting. Because their model presumably had similar limitations, such as the suppression of long-wavelength fluctuations, imposed by the periodic boundaries, comparison of their results with our own seems reasonable. Clearly, however, both approaches should be applied to larger models when this becomes computationally feasible. For the melting temperature 0.75, which is within computational limits of our  $T = 0.77$ , they found  $\rho_{\text{cryst}} = 1.38$  and  $\rho_{\text{liq}} = 1.24$  in our units. Our instability lies at  $\rho_{\text{inst}} = 1.22$  for  $T = 0.77$ . Moreover, their  $\rho_{\text{cryst}}$  and  $\rho_{\text{liq}}$  values rise with temperature much faster than does our  $\rho_{\text{inst}}$ , so the latter would become progressively further removed from Hansen and Verlet's melting interval. This indicates that the observed instability density is not connected with the density at which the critical liquid nucleus becomes comparable in size to the system; if that were so,  $\rho_{\text{cryst}} - \rho_{\text{inst}}$  would be expected to be approximately constant. Furthermore, nucleation, albeit of crystal, has been observed<sup>9</sup> in a system of size comparable with ours. We suggest therefore that there is no essential connection between crystal instability and thermodynamic melting. The observed hysteresis, however, is consistent with approaches to melting which assume no intrinsic correlation between the properties of the crystalline and liquid phases, as discussed recently by Ziman<sup>10</sup>.

Two important variants of the crystal instability approach have involved free volume<sup>11</sup> and dislocations<sup>12</sup>. The present study allows the relative merits of these models to be evaluated.

**Fig. 2** *a*, Pair correlation functions,  $g(r)$ , for the six states indicated in Fig. 1. *b*, Bond-angle distribution functions,  $f(\theta)$ , for the six states indicated in Fig. 1.

**Fig. 3** Potential energy density of states spectra for the normal (solid curve) and hole (dotted curve) states. The three situations (shifted vertically with respect to one another, for clarity) correspond to states A (crystal), F (glass) and E (liquid) indicated in Fig. 1, and the curves extend over the ranges for which states were detectable. For the liquid, the maximum of the normal spectrum lies at  $-5.97$ , while the minimum of the hole spectrum occurs at  $-7.09$ . The curves all have the same (arbitrary) ordinate scale.

The existence of a virtual glass point, located in the thermodynamic density interval for melting, suggests that this transition occurs when the free-energy loss in disordering is just offset by the free-energy gain due to increased atomic mobility. Survival of the crystal at a density lower than  $\rho_{\text{liq}}$  shows that disorder is a prerequisite for such higher mobility, while the isothermal liquid-glass transition reveals the connection between mobility and density in the disordered state. Stimulated by the recent local free-volume approach of Cohen and Grest<sup>13</sup>, we have computed two potential energy spectra: one for actual energies

**Fig. 4** Atomic positions in two adjacent close-packed layers, corresponding to state B of Fig. 1. Linkage reversal, in which the angle subtended at an atom by its immediate neighbours passes through  $180^\circ$  (changing the zig-zag pattern to zag-zig), permits detection of (Shockley partial) dislocations<sup>12</sup>. The dotted line indicates the approximate position of a dislocation loop found in this manner. The long straight lines indicate the periodic boundaries.

of the atoms during the simulation, and one for the energies that atoms would have if moved to the centres of the closest and largest regions of local free volume. These 'normal' and 'hole' spectra for states A (crystal), E (liquid) and F (glass) are shown in Fig. 3. Only for the liquid do the two spectra overlap. In this case, atoms seem to have sufficient energy to take advantage of the choice of position provided by local free volume, and the distinction between normal and hole states is no longer well defined. This is presumably the origin of the enhanced atomic mobility. Finally, using an earlier dislocation-detection procedure<sup>12</sup>, we find that the observed crystal-liquid instability is dislocation mediated. No dislocations were observed at densities above state B, but these defects appeared (and rapidly proliferated) on reaching B, as shown in Fig. 4. This result is in conflict with the dislocation theory of melting.

We thank W. Damgaard Kristensen for stimulating discussions, and the Danish Natural SRC for support.

## Low-temperature preparation of refractory alloys

A. K. Cheetham

Chemical Crystallography Laboratory, University of Oxford,  
9 Parks Road, Oxford OX1 3PD, UK

The escalating cost of energy has stimulated interest in the preparation of refractory and ceramic materials by low-temperature methods. Such methods are particularly attractive for the preparation of catalysts because the products are more finely divided than those obtained from conventional solid-state reactions, and they are also of academic interest because they provide the opportunity to examine some previously inaccessible low-temperature areas of phase diagrams. So far, interest has focused mainly on the synthesis of mixed metal oxides by the ignition of precursors which have been precipitated from aqueous solution<sup>1</sup> or freeze dried<sup>2</sup>, although platinum metal alloys have also been prepared, for example by the reduction of salts which have been impregnated on a silica support<sup>3</sup>. I report here the low-temperature synthesis of the refractory alloy Mo-W by precipitation from aqueous solution followed by hydrogen reduction.

The melting points of Mo and W are  $2,610^\circ\text{C}$  and  $3,410^\circ\text{C}$  respectively. They form a continuous body-centred cubic solid solution in which the lattice parameter varies linearly with composition<sup>4</sup> between  $3.1472\text{ \AA}$  (Mo) and  $3.1648\text{ \AA}$  (W). The alloys are typically prepared from the melt or by sintering the metals in a powder form at  $\sim 2,300^\circ\text{C}$ .

In the present experiments, ammonium paramolybdate,  $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}\cdot 4\text{H}_2\text{O}$ , and ammonium paratungstate,  $(\text{NH}_4)_{10}\text{W}_{12}\text{O}_{41}\cdot 5\text{H}_2\text{O}$ , were dissolved in hot water and then precipitated by adding the cooled solution to a large excess of ethanol. Examination of individual particles of the precipitates by X-ray emission analysis in a Jeol 100CX TEMSCAN analytical electron microscope revealed a surprising degree of homogeneity in the Mo-W distribution at this stage. The alloys

**Fig. 1** X-ray emission spectrum from a thin crystal of  $\text{Mo}_{0.6}\text{W}_{0.4}$  supported on a copper grid. Operating voltage, 100 keV.

were obtained by reducing the precipitates in hydrogen for  $\sim 5$  h at  $700^\circ\text{C}$ ; reduction can even be effected at  $500^\circ\text{C}$  but the product is pyrophoric. The thermal decomposition of the precipitates in air at  $500^\circ\text{C}$  led to the formation of mixed metal oxides in the system  $\text{MoO}_3\text{--}\text{WO}_3$ . The preparation of these oxides has previously been carried out by a solid-state reaction between  $\text{MoO}_3$  and  $\text{WO}_3$  at temperatures up to  $1,100^\circ\text{C}$  for 3 days<sup>5</sup>.

The chemical composition of the alloy may be controlled by changing the composition of the starting solution and samples were prepared at the following compositions: 13, 37, 60, 79, 88 and 94 atom % Mo. Individual alloy particles were examined in the analytical electron microscope to monitor the composition and homogeneity, and Fig. 1 shows a typical X-ray emission spectrum. In the thin-crystal limit, the W:Mo ratio is directly proportional to the ratio of appropriate X-ray emission intensities<sup>6</sup>, for example  $\text{WM}\alpha : \text{MoL}$ , and the results obtained from an examination of several thin crystals at each composition are presented in Fig. 2. The error bars represent the range of  $\text{WM}\alpha : \text{MoL}$  ratios observed at each composition. Two of the alloys, at 37 and 79% Mo, are noticeably less homogeneous ( $\pm 4\text{--}5\%$  Mo) and this is reflected in their X-ray powder patterns which exhibit broader lines. However, the results clearly

**Fig. 2** The measured  $\text{WM}\alpha : \text{MoL}$  intensity ratio for the alloys versus the W:Mo ratio in the starting solution. Use of a log-log plot distributes the points more evenly.

indicate the preparation of alloys across the complete composition range and are in accord with the thin-crystal approximation. The electron optical study also revealed a small particle size in the range  $0.1\text{--}10\ \mu\text{m}$ .

The alloys containing 13, 60, 88 and 95% Mo gave sharp Guinier X-ray patterns with bcc cell constants of  $3.165(1)$ ,  $3.152(1)$ ,  $3.149(1)$  and  $3.147(1)\ \text{\AA}$  respectively. These values agree well with the expected cell constants ( $3.163$ ,  $3.154$ ,  $3.149$  and  $3.148\ \text{\AA}$ ) and confirm that true alloys, rather than biphasic mixtures of Mo and W, have been formed.

It is surprising that the degree of homogeneity observed in the precipitate can be obtained by precipitating two ammonium salts which apparently contain polyanions of different stoichiometries, that is  $\text{Mo}_7\text{O}_{24}^{6-}$  and  $\text{W}_{12}\text{O}_{41}^{10-}$ . However, a modification of sodium tungstate containing the  $\text{W}_7\text{O}_{24}^{6-}$  ion has been prepared by boiling aqueous solutions of sodium paratungstate<sup>7</sup> and it is possible that the initial heating step in the procedure described above results in the formation of heteropolyanions of the type  $(\text{Mo}_{7-n}\text{W}_n\text{O}_{24})^{6-}$  so that a rather homogeneous distribution of the metals is frozen in before precipitation.

The alloy synthesis described here may be adapted for the preparation of a wide range of alloys containing metals which can normally be obtained by hydrogen reduction of an appropriate compound. This group comprises almost all the metallic elements to the right of molybdenum and tungsten in the Periodic Table. The method of precipitation will clearly depend on the particular elements involved and, in some cases, milder reducing conditions may be appropriate. The most exciting application of the procedure is likely to be in catalysis where the small particle size obtained in a low-temperature synthesis is particularly advantageous.

I thank Dr Michael Pope for a useful discussion, Mrs Ann Stoker for technical assistance and the SRC for grant GR/A/3320 towards an electron microscope.

**Note added in proof:** My coworkers and I have recently demonstrated that alloys in the systems W-Re, Pt-Ru and Fe-Ni can be prepared by related methods.

## Geometry of transform zones

Hans Schouten, Jeff Karson & Henry Dick

Department of Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

**Asymmetric sea-floor formation at oceanic spreading centre/transform fault intersections is predicted by the steady-state (average) geometry of finite-width transform fault zones. In the central North Atlantic, geological and geophysical data near both small-offset (FAMOUS Fracture Zone B) and large-offset (Kane Fracture Zone) transforms support this geometry. We report here observations made on both regional and local scales which suggest predictable systematic development of asymmetric features in these areas.**

Sea-floor spreading occurs along mid-ocean ridges<sup>1</sup>. These oceanic rift zones form the continuous boundaries between diverging lithospheric plates. To a first approximation, the plates are rigid—major deformation occurs only at their boundaries<sup>2</sup>. The diverging or accreting boundary between two plates consists of a string of discontinuous elongate spreading-centre segments

**Fig. 1** Three successive transform fault events on a divergent plate boundary. The dashed lines mark the 95% width of the active plate boundary. Successive strike-slip faults and corresponding rifts (heavy double lines) are randomly distributed about their respective median axes. Half the time rifting will extend beyond the median axis of the transform fault zone. The steady-state (average) geometry of a transform zone formed by a succession of these events is shown in Fig. 2.

where young oceanic crust is accreted in a predominantly extensional regime. The extensional segments are joined by transform fault zones<sup>3</sup> which represent a regime of predominant shear displacement, parallel to the direction of spreading. Spreading centres have a typical width of 2–10 km (refs 4, 5) over which most of the volcanic emplacement of oceanic crust occurs, whereas extensional tectonic deformation may be active over a broader zone<sup>4</sup>. Based on observations from manned submersibles and deep-towed instruments, the time-integrated width of crust affected by tectonic deformation in Atlantic transform fault zones may be as much as a few tens of kilometres<sup>6–8</sup>. At a given time, however, strike-slip activity in a transform zone may be restricted to a single fault<sup>9</sup> but averaged over a longer period of time (steady state), strike-slip deformation will have affected a zone of finite width (see Fig. 1).

We consider now the steady-state (average) configuration of a finite-width transform zone. Let the strike-slip activity be randomly distributed about the median axis of the transform zone. The assemblage of strike-slip faults constitute transform faults which, as Wilson<sup>3</sup> pointed out, provide the continuity of the active plate boundary between spreading-centre segments on either side of the transform. Following Wilson's definition, strike-slip transform activity terminates in extensional activity at both ends. Thus, if transform fault deformation occurs over a zone of finite width, then, logically, half the time the rift termination will extend beyond the median axis of the transform zone (see Fig. 1).

Figure 2a shows the steady-state model of a finite-width transform zone that offsets two spreading-centre segments. The numbered isochrons illustrate the steady-state geometry and asymmetric evolution of the sea floor in a transform zone. Consecutive isochrons describe progressive stages of strike-slip deformation of the linear isochrons formed originally in the spreading centres of Fig. 2a. This geometry has been computed for strike-slip transform activity that is normally distributed about the median axis of the transform zone with standard deviation  $\sigma$ . Thus, 95% of the strike-slip activity occurs within  $4\sigma$ , or there is a 95% probability that strike-slip activity will occur within  $\pm 2\sigma$  from the median axis. The total spreading rates in the individual spreading centres are shown in Fig. 2b. The rigid-plate geometry requires that the sum of the total spreading rates in the direction of spreading is a constant everywhere on the accreting boundary. At the median transform axis, the contribution to the total spreading for both spreading-centre segments is equal. Thus, up to the median transform axis, the spreading velocity must remain constant on one side of the spreading centre (outside the active transform zone) while on the other side, spreading decreases to zero at the median axis (Fig. 2a). In other words, at the intersection of a spreading centre with a transform zone, accretion of sea floor should become progressively asymmetric until it is fully asymmetric at the median axis. Beyond the median transform axis, extension and magmatism could propagate into crust that was formed originally at the other spreading centre, resulting in mixing of young crustal material with older crust that has a transform-deformation history.

The steady-state geometry in Fig. 2a predicts that the average age of the sea floor in the transform zone will be older than that of the surrounding sea floor. The inactive trace of the transform zone will be only half the width of the active transform and will consist of mixed-age oceanic crust. Sea floor formed in the transform-zone segment of the spreading centres will have no

**Fig. 2** a, Steady-state (average) geometry of a finite-width transform zone that offsets two spreading centres (heavy double lines). This geometry has been computed for strike-slip transform fault activity that is normally distributed about the median axis of the transform zone with standard deviation  $\sigma$ . The numbered isochrons illustrate the asymmetric evolution of the sea floor in a finite-width transform zone. Note the mixed-age isochrons in the inactive parts of the transform. Hachures indicate sea floor with transform deformation history. b, Total spreading rates in each spreading centre. Rigid-plate geometry requires that the sum of these total spreading rates is a constant everywhere along the plate boundary.

**Fig. 3** Asymmetric bathymetry and marine magnetic anomalies 2' (stipples, after ref. 11) in FAMOUS Fracture Zone B. Depth contours are in fathoms. Active spreading axes (after ref. 11) are indicated by heavy double lines. The asymmetric transform zone geometry of Fracture Zone B is illustrated by a pattern of hachures explained in Fig. 2. Similar geometries can be drawn for Fracture Zones A and C.

matching counterpart on the opposite plate—the distribution of youngest volcanics at the transform intersection will be highly asymmetric and marine magnetic anomalies (isochrons) will not match.

Although this model may not be applicable to all classes of ridge-ridge transform faults, geological and geophysical data from two separate areas agree with this geometry. The first is the FAMOUS detailed survey located at latitude 36.5°N on the Mid-Atlantic Ridge crest between the Azores and the Oceanographer Fracture Zone. The bathymetry<sup>10</sup> and segments of marine magnetic anomaly 2' (stipples)<sup>11</sup> around FAMOUS Fracture Zone B are shown in Fig. 3. The active transform section of Fracture Zone B offsets the Mid-Atlantic Ridge ~20 km in a right-lateral sense. Focal mechanism solutions of earthquakes and structural trends in the FAMOUS fracture zones suggest an east-west direction of relative plate motion in the central North Atlantic<sup>12,13</sup>. We assume the east-west direction of spreading has been active since magnetic anomaly 2' (3 Myr BP). A relevant feature of the bathymetry (Fig. 3) is the

existence of parallel extensions of the adjacent spreading centres in Fracture Zone B and an asymmetric distribution of the fracture zone valleys<sup>11,14</sup>. In the magnetic anomaly pattern, northwestern anomaly 2' terminates at the (steepest) northern wall of the western fracture-zone valley whereas northeastern anomaly 2' continues across the eastern fracture zone and terminates at the (steepest) southern wall of the valley.

These observations of Fracture Zone B suggest a 20-km wide transform-zone geometry (hachures in Fig. 3) that has been active during the past 3 Myr of central North Atlantic sea floor spreading. The transform-zone segment of northeastern anomaly 2' has no matching counterpart on the western plate. According to the model, young sea floor formed in the transform zone at the northern spreading centre will be transported to the east undeformed, but to the west it will be deformed in the active transform zone and then overprinted when it passes through the southern spreading centre. In this small-offset transform zone, spreading-centre activity seems to extend well beyond the median transform axis as indicated by the echelon rift valley

**Fig. 4** Generalized geology of the Kane Fracture Zone. Bathymetric contours in metres, 500-m interval (after ref. 16). ●, Dredge haul locations; bold hachured lines, Angus camera runs (after ref. 8); scalloped pattern, young pillow basalts with negligible pelagic cover; dashed pattern, transform zone lithologies including basalt, metabasalt, greenstone, gabbro, metagabbro, serpentinite and various breccias; no pattern, areas of older basalts with variable cover of carbonate ooze. Asymmetric pattern of hachures (as in Figs 2 and 3) indicates the inferred extent of crust affected by transform tectonics.

extensions and the northeastern segment of anomaly 2'. This suggests that the physical properties of the deformed lithosphere within the transform zone at the ridge intersections are not significantly different from the physical properties of the lithosphere in spreading centres outside of transform zones and that spreading may occur in both areas.

The active transform section of the Kane Fracture Zone offsets the Mid-Atlantic Ridge approximately 160 km in a left-lateral sense near latitude 24° N (see Fig. 4)<sup>15-18</sup>. The fracture-zone valley is outlined by the 4,000-m contour in Fig. 4 and has a width of 10–20 km over most of its length. Combined dredging and acoustically navigated bottom camera *Angus* surveys in the fracture zone reveal an asymmetric distribution of young pillow basalts with respect to highly altered and faulted lithologies as well as the major tectonic features at the ridge intersections<sup>16</sup>.

Fresh pillow basalts with negligible pelagic cover are exposed in the median rift valley floors and at the base of the older walls in the transform zone opposite both ridge intersections (scaloped pattern in Fig. 4). Fissures and faults in the young pillow lavas at the intersections indicate extension normal to the regional trend of the spreading centre<sup>8</sup>. Thus, sea-floor spreading seems to be continuous across the Kane Fracture Zone valley at the ridge intersections.

Pillow basalts with a variable cover of calcareous ooze occur along the median rift valley walls and marginal highs north and south of the fracture zone. Pillow basalts are also found on the floor and up the younger walls of the fracture zone outside the transform region (no pattern in Fig. 4). However, the walls of the active transform zone, the older fracture zone walls outside the transform, and oblique-trending median valley walls near the intersection provide exposures of a variety of lithologies including basalt, metabasalt, greenstone, gabbro, metagabbro, serpentinite and various breccias (dashed pattern in Fig. 4). Most of these lithologies are variably fractured and covered with ferromanganese crusts.

The asymmetric distribution of pillow basalts is best documented at the western Kane intersection where *Angus* coverage is more extensive (see Fig. 4). Relatively fresh pillow lavas extend down the fracture-zone valley a considerable distance to the west. Immediately to the east of the western intersection, the floor of the transform is largely covered with sediments and a few older appearing outcrops of brecciated rock. *Angus* coverage of transform zone lithologies immediately to the west of the eastern Kane intersection and fresh basalts dredged at the base of the older wall in the transform zone opposite the eastern ridge intersection suggests a similar asymmetry. We indicate the proposed transform zone geometry with hachures in Fig. 4. The relative abundance of plutonic and metamorphic rocks dredged from the older walls in the transform zone opposite the ridge intersections indicates little if any recent volcanism in these areas. The young volcanics in the fracture-zone valley terminate abruptly against old deformed crust that is passing out of the active Kane transform zone. In contrast to the small-offset FAMOUS Fracture Zone B, extension and magmatism do not seem to continue across the width of the large-offset Kane transform zone, but presumably terminate near the median transform axis. The age contrast across transform zones probably controls the nature and extent of the rifting that propagates into older crust at ridge-transform intersections.

In conclusion, these studies show that various asymmetric aspects of some ridge-transform intersections on the Mid-Atlantic Ridge can be explained by a steady-state geometry of transform fault zones that are a few tens of kilometres wide. The agreement between observations and steady-state model suggests that even on a 10-km scale, the process of sea-floor formation along an accreting boundary can be considered more uniform than random.

## Subduction of the Iapetus Ocean crust beneath the Møre Gneiss Region, southern Norway

S. Mykkeltveit\*, E. S. Husebye\*† & C. Oftedahl‡

**Basement–cover relations between Caledonian nappes and underlying Precambrian basement along the western coastline of southern Norway have long intrigued geologists and considerable progress has recently been made in understanding the Caledonian geology<sup>1–3</sup>, geochronological studies proving particularly useful. For example, the Precambrian gneisses along the coast from Bergen to Namsos yield ages up to 1,700 Myr, supposedly the age both of the formation of the rocks and the main metamorphism and deformation phases<sup>4</sup>. The Lofoten–Tromsø archipelago is a presumed continuation of this basement block once sandwiched between the Caledonides of Norway and Greenland. An important phase of rock formation and metamorphism affected the gneisses here at around 1,800 Myr, whereas subsequent orogenies at 1,100 and 400 Myr (Grenville–Sveco-Norwegian or Dalslandian, and late Caledonian orogenies, respectively) had little effect. COCORP reflection profiling in the southern Appalachians<sup>5</sup> has demonstrated that crystalline ‘basement’ has been thrust for a large distance over autochthonous early Palaeozoic sediments of the proto-Atlantic continental margin. Data from a seismic profile<sup>6</sup> across the Møre Gneiss Region (often called the northwestern basal gneisses of southern Norway) show evidence of P-wave velocity reversal at a depth of about 14 km, and the associated low-velocity layer (LVL) has a thickness of 4 km. As there is no excess of heat flow to account for the LVL, we consider here the hypothesis that oceanic crust and accompanying sediments have been subducted under the gneisses.**

The refraction–wide-angle reflection seismic profile is indicated in Fig. 1, together with the two shot-point locations I and II. Five 3-component seismometers were moved along the profile at an average spacing of 2.5 km, while explosive charges of 25–300 kg were fired in water depths of ~20 m at the shot points. Altogether 145 seismic field records were obtained, but many of them were not suitable for detailed digital analysis, although several poorer-quality records were used for extracting first arrival travel times.

After the necessary elevation corrections had been made, a Herglotz–Wiechert inversion procedure was applied to the first

**Fig. 1** Simplified tectonic map of Norway redrawn after Reymer<sup>7</sup>, showing shot points I and II of the seismic profile crossing the Møre Gneiss Region. 1, Precambrian basement, including the generally presumed autochthonous Møre Gneiss Region, with radiometric ages in the range 1,900–1,200 Myr; 2, mostly Precambrian nappes (1,200–850 Myr) also including structures of Caledonian ages; 3, Lower Palaeozoic elements, (par)-autochthonous-allochthonous structures of mostly Cambrian–Silurian ages; 4, Lower Palaeozoic elements, typical nappe substructures having a presumed south-eastern direction of thrusting.

arrival observations (see Fig. 2a). The continuously increasing velocity distribution obtained (Fig. 2b) was truncated at 12–14-km depth, because the pronounced offset in the travel-time curves suggests the existence of a LVL in the upper crust. Note that strong lateral inhomogeneity effects are ruled out by detailed comparison of records from the two shot points.

Modelling of the lower crust is relatively uncertain in view of a maximum shot-detector separation of 190 km. The outstanding feature, however, of the velocity model obtained is the roughly 4-km thick LVL in the upper crust. Because of objections to such a feature on the grounds of both realistic heat-generation mechanisms and limited resolving power of our data, we have undertaken extensive synthetic seismogram analyses. These experiments demonstrate that the most appropriate model for reconciling discontinuous travel-time data and amplitude distributions of primary and secondary phases involves the introduction of a LVL, which can generally be recognized best from reflections from the top of it. Characteristics of these arrivals are: (1) a 180° phase shift relative to the first arrivals; (2) the travel time and apparent velocity; and (3) absence of associated head-wave arrivals<sup>8</sup>. Figure 2c shows an extract from both the observed record section (shot point I) and a synthetic section computed from the model in Fig. 2b, covering the distance interval over which the LVL reflections are observed. The upper-crustal first arrivals (d) and the reflections from the top and bottom (e and f respectively) of the LVL are well modelled by the synthetic section.

From our data it is impossible to estimate accurately the actual horizontal extent of the LVL, even in the direction of the profile. Our modelling experiment here demonstrates that, even if the LVL were present under the entire profile, the reflections would

be observable only where they are actually seen in the record section. However, a minimum extent of the LVL can be estimated and is indicated by AB in Fig. 1. The data also suggest that the LVL is rather flat-lying. The two velocity–depth curves of Fig. 2b can be taken to be representative at points A (curve I) and B (curve II) of Fig. 1, some 50-km apart, yielding a westward dip of the upper LVL interface of <2°.

The nature and significance of low-velocity zones are still not well understood. Extensive laboratory experiments have been undertaken to investigate the possibility of crustal velocity reversals. The main prerequisite for such phenomena is either anomalously high temperatures and/or profound compositional changes. Typical examples are areas of exceptionally high heat flow such as rift zones and areas, where high-velocity crystalline rocks have been thrust over 'soft' material of lower velocity<sup>9,10</sup>. Within the Møre gneisses there is no evidence of high heat flow<sup>11</sup>, so the postulated LVL must be associated with compositional changes. Further to the north near Mo i Rana, a trans-Scandinavian profile<sup>12</sup> also gives evidence of an upper-crustal velocity reversal under the Caledonides only (see Fig. 1).

We suggest that the crustal structure in the Møre Gneiss Region is explained by a doubling of the crust, which occurred during the final continent–continent collision of the Caledonides towards the end of the Silurian. As low-velocity rocks, sandwiched between continental rocks from two opposing continents, two types must be considered: (1) serpentinites, and (2) eugeosynclinal sedimentary rocks of relatively low metamorphic grade. It is impossible to discriminate between types (1) and (2) from the geophysical data only. Type (1) is, however, discarded because of the geological improbability of having serpentinite from the lower oceanic crust as a surface layer on top of the lower continental mass. Logically the

**Fig. 2** a, First arrival travel times for both shot points. The continuous curves represent a slight smoothing of travel-time observations. b, Velocity–depth distribution derived from shot point I data. Dashed curve, shot point II data. c, Detail of record section (top) for shot point I and corresponding synthetic section (bottom). Selected segments of the travel-time curves as computed from the model of b (curve I) are inserted.

**Fig. 3** Simplified cross-sections through the Møre Gneiss Region, with the closing of the Iapetus Ocean, illustrating our hypothesis for the LVL. *a*, Late stage in the closing of the Iapetus Ocean. *b*, Situation before the continents collide, with a westerly dipping subduction zone along which orogenic sediments are dragged down. *c*, The continental collision resulting in doubling of crustal thickness with sediments constituting the LVL sandwiched between the two crustal blocks. *d*, A westerly Himalayan-type mountain chain resulting from isostatic uplift, off which the nappes glide to the east.

incorporation of eogeosynclinal sediments during subduction should occur during a subduction process<sup>13</sup>. This hypothesis contrasts with the current thinking of many geologists working with the basement-cover relations of the Caledonides in southern Norway, who favour the view that the Møre gneisses represent an autochthonous area above which Caledonian nappes to the east have been thrust from a westerly location in the Lower Palaeozoic proto-Atlantic (Iapetus) ocean<sup>4,14</sup>.

Our hypothesis relies on the general features of the Bergen-Namsos area, which exhibits a lithological and structural development clearly different from that of southeastern Norway<sup>3</sup>. This area may either be classed as a separate Precambrian block<sup>15</sup>, or may represent an overthrusting part of the American block over the Eurasian one. In the latter case, a last deformation of the Precambrian gneisses has to be of Caledonian age. This possibility is permitted by a recent Sm/Nd age study<sup>16</sup> of eclogite lenses located in granitic gneisses in the coastal Møre area, which are found to be late Ordovician-Silurian.

A mechanism envisaging a Himalayan-type doubling in thickness of the crust of the mid-Scandinavian Caledonides is sketched in Fig. 3, based on recent suggestions for the Grenville collision<sup>17</sup> and the Sunda trench subduction<sup>13</sup>. The allochthonous overthrust block of the Møre gneisses may not be restricted to the Bergen-Namsos area, but may include the basement of the whole Nordland coast as well as the Precambrian of the Lofoten-Tromsø coastal area. The buoyancy of the doubled continental crust would have produced a Himalayan-type mountain chain, off which slid the soft Cambro-Silurian orogenic rocks as nappes travelling far to the east—250–500 km, possibly even further<sup>18,19</sup>. The weathered core of this chain now exhibits the eclogites. The postulated collision zone to the east of the Møre Gneiss Region (the 'Jotunheimen suture') is supported by recent detailed geological field work<sup>20</sup>. Also, a recent Fennoscandian study<sup>21</sup> supports the idea of a relatively thick crust (~40 km) in the coastal areas of

western and northern Norway, as opposed to southeastern Norway (Oslofjord), where the Moho depth is only around 30 km. Finally, some features of our model have earlier been hinted at<sup>3</sup> and also used to explain the surprisingly young age of the Møre eclogites<sup>16</sup>.

Although our interpretations of the LVL beneath the Møre Gneiss Region may be considered premature, we conclude that the identification and interpretation of similar crustal velocity reversals will have an important application to the problem of unravelling continental collisions and locating the sutures between them.

## Guidance system used in moth sex attraction

J. S. Kennedy\*, A. R. Ludlow & C. J. Sanders†

ARC Insect Physiology Group, Department of Zoology and Applied Entomology, Imperial College of Science and Technology, London SW7 2AZ, UK

It has been proposed<sup>1–4</sup> that a flying male moth finds its way to a 'calling' female or other small, distant source of wind-borne sex pheromone using two contrasting anemotactic manoeuvres: (1) upwind flight in response to the onset or increase of the pheromone stimulus, maintained as long as the stimulus continues, and (2) cross-wind flight with switching between left and right of the wind line (the so-called 'track reversals'<sup>4</sup> or 'tack reversals'<sup>5</sup> seen in casting or zig-zagging) which occurs only in response to the loss or decrease of the pheromone stimulus. A simpler system can now be proposed in the light of wind-tunnel experiments on male summerfruit tortrix moths (*Adoxophyes orana*) entering homogeneous pheromone clouds. The moths did not fly persistently upwind with continuous pheromone stimulation, and their programmed left-right track reversals occurred in response to pheromone onset, not loss, and continued after pheromone loss but with widening cross-wind excursions between reversals.

† Present address: Great Lakes Forest Research Centre, PO Box 490, Sault Ste. Marie, Ontario, Canada PLA 5M7.

**Fig. 1** Samples of flight tracks in the wind tunnel. Time marks at 0.5 s intervals. 0.1-m scale bar and wind direction arrowhead in *a* apply to all tracks. *a, b*, Cross-wind casting after removal of a pheromone plume, leading to entry into the pheromone corridor (hatched) and a brief upwind advance, followed by resumed casting. *c*, Same as above but entry into the pheromone corridor followed only by narrowed casting without upwind progress. *d*, A normal, structured, pheromone plume (broken lines indicate its smoke-simulated, time-averaged outer envelope) added to a pheromone cloud filling the entire tunnel—on encountering this plume the casting moth 'locks-on' to it and advances upwind along it as if the plume were in clean air.

The male moths were held in constant light without females for 3–4 days from emergence and then in darkness for ~2 h before transfer to the wind-tunnel<sup>4</sup> (working section  $1.9 \times 1.2 \times 0.45$  m) in ~12 lx from overhead fluorescent lamps and a smooth air flow of  $\sim 0.24 \text{ m s}^{-1}$ . The pheromone was not presented to the flying moths in the normal form of a broken, filamentous plume because it is then impossible to say when the flier is and is not meeting pheromone, and stimulus-response relations cannot be identified. In these experiments, therefore, the pheromone was presented as a homogeneous cloud. The pheromone cloud filled a floor-to-ceiling 'corridor' about 0.36 m wide against one wall of the tunnel, and smoke simulation showed a sharp boundary with negligible mixing between this 'corridor' air and the contiguous body of clean air moving in parallel down the rest of the tunnel.

The following procedure was used to select only responsive moths and to ensure they received the pheromone test-stimulus (by entering the corridor) in a standard and observable manner. Each moth was first exposed to the normal type of plume from a small pellet of polyvinyl chloride containing synthetic pheromone (a 9:1 mixture of *trans*- and *cis*-11-tetradecenyl acetate) in the clean part of the tunnel. Moths were discarded unless they responded by taking off, 'locking-on' to the plume (that is, heading into wind and restricting their cross-wind movements to the immediate vicinity of the plume) and then advancing up it for more than 1 m, keeping away from the side corridor of diffuse pheromone. Each moth that responded in this way was then induced, by suddenly removing the pheromone plume, to stop advancing upwind and to cast across wind increasingly widely<sup>2,4</sup> and so enter the side pheromone corridor within a few seconds. A control set of moths were treated in the same way in the absence of pheromone corridor. The horizontal component of the flier's movements was recorded on videotape, and the position and time of each track reversal (switching from one side of the wind-line to the other) were later read to provide data on the cross-wind extent, duration and net direction of each inter-reversal leg of the track. The tracks were also traced frame by frame to determine the incidence of upwind advances. For this purpose an upwind advance was defined as a section of the flight track that continued with no downwind movement at all until upwind progress of at least 0.2 m had been made. Such advances often comprised zig-zags (Fig. 1*a*) but without the track deviating from due upwind by more than 90°.

Twenty-nine moths were recorded with the side pheromone corridor present. They flew in and out of it repeatedly and 40 of

their entries were made after they had spent more than 2 s outside it. 35% (14) of these entries were followed directly by an upwind advance as defined, as against 5% (5) of 93 equivalent legs in the control series without any pheromone cloud ( $P < 0.001$ ). The time from crossing the border into the pheromone corridor to the next track reversal averaged about 0.2 s, and an upwind turn was already evident in the mean angle to wind of the 40 legs starting then. Taking due upwind as 0°, this angle was  $70.0 \pm 4.2$  (30% of legs at  $< 60^\circ$ ) as against  $87.0 \pm 1.1^\circ$  (all legs  $> 60^\circ$ ) in the controls. By contrast, there was no significant upwind response when the moths entered the pheromone corridor after spending less than 2 s outside it. Only 2% (7) of these 438 entries were followed by an upwind advance, significantly less than the figure of 35% after more than 2 s outside ( $P < 0.001$ ).

**Fig. 2** The cross-wind component of one moth's flight track in the wind tunnel, plotted against time. Only the positions at which the track reversed across wind were measured, the straight lines joining these reversal points being interpolations. The broken line marks the approximate position of the border between the 'clean' part of the airflow and the pheromone 'corridor' extending to the tunnel wall at 120 cm. Note frequent track reversals inside the pheromone corridor, which cannot be attributed to any change in pheromone stimulation.

The lack of response on re-entering the pheromone after less than 2 s outside it implies that the moths were then adapted (*sensu lato*) to the given pheromone stimulus, at least in respect of the upwind flight response, and that substantial disadaptation required more than 2 s in clean air. A second indication of adaptation was that the upwind advances were mostly brief, of the order of 1 s, the moth then reverting to cross-wind casting and 'keeping station' against the wind as in Fig. 1a and b. This arrest of upwind progress could not be attributed entirely to a high pheromone concentration in the corridor although high concentrations are known to retard upwind flight along pheromone plumes<sup>4-6</sup>. These same moths had all progressed freely up the broken plume from the single-pellet pheromone source shortly before, and the pheromone concentration in the individual filaments of the plume will have been higher than in the corridor cloud. In a parallel treatment, 26 moths, casting widely after plume removal as before, were engulfed by a wind-borne, homogeneous pheromone cloud that was not confined to a side corridor but filled the entire tunnel. Again there were brief upwind advances with reversion to cross-wind casting, although the cloud concentration was at least 30 times less than the mean concentration in the plume up which these same moths had progressed freely just before. Furthermore on several occasions when moths had been casting and making no progress for many seconds within such a ubiquitous pheromone cloud, they were also presented with a normal, broken, pheromone plume from a single pellet. On encountering this superimposed plume the moths promptly 'locked on' to it and advanced up it in zig-zags (Fig. 1d) in the same manner as they had done when presented with the same plume in otherwise clean air. Evidently the moths were adapted to the pheromone concentration in the cloud but still fully responsive to increases above that level.

Entries into the side pheromone corridor, or the ubiquitous pheromone cloud, led not only to some upwind advances but also, and much more predictably, to a restriction of cross-wind movement. This was not mainly due to turning upwind although that, of course, enhanced the effect. When combined with an upwind advance, the restriction produced narrow upwind zig-zagging as in Fig. 1a. More frequent was a simple narrowing of the cross-wind casting already in train, without upwind progress, as in Fig. 1c. The narrowing was due mainly to a reduction of flight speed rather than time interval between track reversals, and it persisted for at least 2 s in clean air after emergence from the pheromone corridor. As a result of this persistent, pheromone-induced narrowing the moths' movements became concentrated around the free border of the pheromone corridor and often crossed it in both directions (Figs 1a-c, 2). Thus there were many instances of turning back into the pheromone corridor after leaving it, but there were also many cases of two or more consecutive track reversals entirely inside the pheromone corridor (Figs 1a, 2). This contradicts the above theory that track reversal is a response to losing the scent. There were a total of 224 cases of moths moving across the inside of the pheromone corridor towards its free border with the clean air, but then turning back well before reaching the border. Furthermore the 26 moths engulfed in the ubiquitous pheromone cloud already mentioned made an average of 27 (3-59) consecutive track reversals each, all without any pheromone decrease.

We conclude that persistent upwind flight requires decreases as well as increases of the pheromone stimulus and that the programmed switching of the flight track between left and right of the wind-line, seen in zig-zagging and casting flight, is not a response to loss of pheromone. It is initiated by pheromone, and then modulated by pheromone changes, the amplitude of these cross-wind movements changing inversely with the strength of the pheromone stimulus. This would provide a simpler guidance system than those previously proposed.

We thank Dr P. Gruys for the regular supply of moth pupae, Dr S. Voerman for the synthetic pheromone and Mr J. G. Ions for technical support.

## Environmentally dependent sensitive periods for avian vocal learning

Donald E. Kroodsma\* & Roberta Pickert

Rockefeller University Field Research Center, Millbrook, New York 12545

**Experience during brief periods of development can exert a profound influence on later life<sup>1</sup>. Among songbirds, experimental evidence for enhanced vocal learning during a relatively brief period early in life is well documented<sup>2,3</sup>. The timing of vocal learning with respect to dispersal is fundamental to our understanding of many population processes, yet the significance of the sensitive period remains unclear. We report here that in our study of the marsh wren (*Cistothorus palustris*), a North American songbird, we found that the sensitive period for song learning is not rigidly programmed with respect to dispersal and/or migration; two environmental factors, the photoperiod and the amount of adult song heard during the hatching year, influence the nature of the sensitive period during the hatching year, the ability to learn further the next spring, and the relative dates at which young males develop their adult songs.**

In our Hudson River marsh, nestling wrens hatch from mid-June to late August. Young hatched early in the year hear many adult songs and experience long days through June and July, and two previous laboratory experiments had indicated that song learning in these conditions seemed restricted to the first 60-80 days of life<sup>4</sup>. Young hatched late in the year, however, hear few if any adult songs<sup>5</sup> and experience relatively short days during the first couple of months. If these late-hatched young are to sing and breed the next year, their learning period must also be delayed until the following spring.

To test the possible effects of the photoperiod and exposure to song on the timing of the sensitive period, during early July we collected 18 nestling males from our Hudson River marsh at 41° north latitude. These were placed in sound isolation chambers; 10 males (hereafter called June males) were placed on a photoperiod simulating an early June hatching, whereas the remaining 8 males (August males) were on a photoperiod simulating an early August hatching. Thus, mean ages for the two groups were the same, and subsequent changes in daylength for each photoperiod group matched that of the home latitude. Each photoperiod group was further subdivided into three experience treatments: from roughly days 20 to 100 (Fig. 1), some males were tutored with two different song types every 5 days (a total of 32 song types; three June and two August males), some with one song type every 5 days (16 song types, four June and four August males), and some heard no songs during their hatching year (three June and two August males). During development of their adult songs the next spring all 18 males were exposed daily to 12 additional song types.

The physiological effects of the two photoperiod treatments were substantial (Fig. 1). Median ages for onset and termination of moult in the August males were 45 and 71 days compared with 62.5 and 95 days for the June males. Early morning practice singing (subsinging) also revealed that the autumn period of

\* Present address: Department of Zoology, University of Massachusetts, Amherst, Massachusetts 01003.

subsong was sharply curtailed in the August males; thus, between days 70 and 140, 72-min recordings from each male revealed subsong for a median period of only 11 min for August males but 54 min for June males. The quality of this subsong during the autumn period differed substantially between groups: the August males never passed a very rudimentary rambling characteristic of the very earliest stages of song development, but many of the June males developed more advanced and stable songs. Finally, the 'migratory restlessness' of the August males began and ended much earlier than that of the June males.

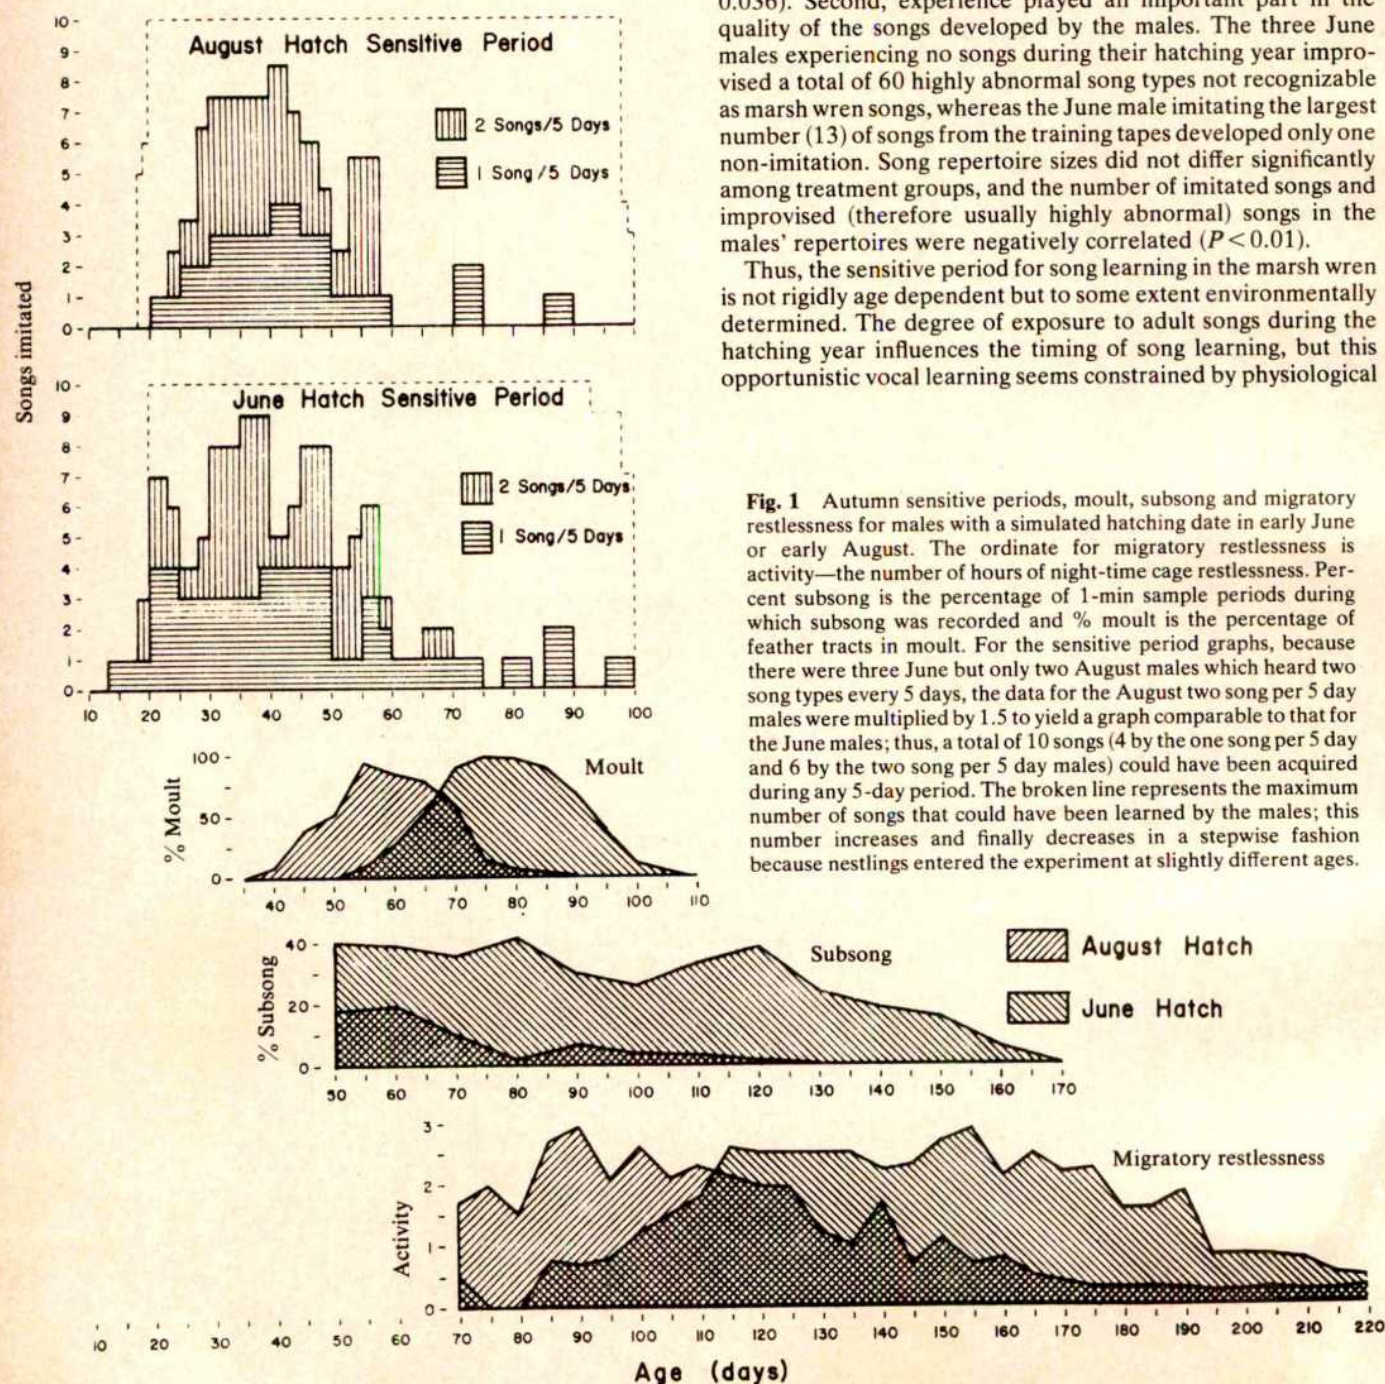

Despite the photoperiodic effects on moult, subsong and migratory activity, the sensitive periods for vocal learning during the autumn did not differ significantly between the two groups; June males seemed to learn<sup>4</sup> more songs and learn them at a later age than August males ( $P=0.1$  in both cases; 1-tailed Mann-Whitney  $U$ -test). August males acquired appreciable repertoire sizes in daylengths when songs in the wild would not normally be available to them. There was a significant difference the next spring, however, as four of the eight August males

imitated songs from the spring training tapes, whereas none of the 10 June males did; the probability of all four of the spring imitators being August males by chance alone is only 0.023.

Those four August males which learned spring songs included two males with no autumn tutoring and two males hearing only one song every 5 days during autumn. The spring learners tended to be the August males which had acquired the fewest imitations during their hatching year ( $P=0.06$ ). In addition, in both photoperiod treatment groups, those males experiencing no songs during their hatching year were the last to develop their final songs the next spring ( $P=0.018$  and  $0.05$  for June and August males, respectively), indicating that lack of exposure to songs can actually delay song development.

Experience with tutor songs during the autumn affected two other features of vocal learning; first, the autumn sensitive period was extended in males hearing fewer songs, as males hearing only one song every 5 days acquired their autumn imitations at a slower rate than the males hearing two songs every 5 days. By day 60, there was a significant difference in the fraction of the final repertoire which had been learned ( $P=0.036$ ). Second, experience played an important part in the quality of the songs developed by the males. The three June males experiencing no songs during their hatching year improvised a total of 60 highly abnormal song types not recognizable as marsh wren songs, whereas the June male imitating the largest number (13) of songs from the training tapes developed only one non-imitation. Song repertoire sizes did not differ significantly among treatment groups, and the number of imitated songs and improvised (therefore usually highly abnormal) songs in the males' repertoires were negatively correlated ( $P<0.01$ ).

Thus, the sensitive period for song learning in the marsh wren is not rigidly age dependent but to some extent environmentally determined. The degree of exposure to adult songs during the hatching year influences the timing of song learning, but this opportunistic vocal learning seems constrained by physiological

**Fig. 1** Autumn sensitive periods, moult, subsong and migratory restlessness for males with a simulated hatching date in early June or early August. The ordinate for migratory restlessness is activity—the number of hours of night-time cage restlessness. Percent subsong is the percentage of 1-min sample periods during which subsong was recorded and % moult is the percentage of feather tracts in moult. For the sensitive period graphs, because there were three June but only two August males which heard two song types every 5 days, the data for the August two song per 5 day males were multiplied by 1.5 to yield a graph comparable to that for the June males; thus, a total of 10 songs (4 by the one song per 5 day and 6 by the two song per 5 day males) could have been acquired during any 5-day period. The broken line represents the maximum number of songs that could have been learned by the males; this number increases and finally decreases in a stepwise fashion because nestlings entered the experiment at slightly different ages.

consequences of the photoperiod; irrespective of early song treatment, only males which were raised under daylengths simulating a late season (August) hatching learned songs the next spring. Nottebohm<sup>6</sup> may have simulated this late season effect to an extreme degree when he castrated a young chaffinch (*Fringilla coelebs*) and delayed the sensitive period for song learning until administration of exogenous testosterone. Thus, in late hatching males low levels of testosterone and/or reduced singing, controlled by the photoperiod, are undoubtedly important factors in delaying the sensitive period.

Among songbird populations, late-hatched young necessarily hear fewer adult songs during the hatching year<sup>5</sup> and often disperse further to the first breeding territory than the early hatched young<sup>7</sup>. A sensitive period which is in part environmentally determined will allow the dispersing juvenile some flexibility in when and where it learns a local song dialect and establishes its territory. Marsh wren juveniles can disperse over considerable distances<sup>8</sup>, and the timing of vocal learning has undoubtedly co-evolved not only with juvenile dispersal strategies but also with adult site-fidelity and habitat stability, large song repertoires, the highly complex male-male vocal interactions<sup>9,10</sup> and other life-history parameters of marsh wren breeding populations. These parameters vary between populations, both within and among species<sup>11,12</sup>, and will, through natural selection, influence the nature of the sensitive period for song learning.

## Sensory maps in the claustrum of the cat

C. R. Olson & A. M. Graybiel

Department of Psychology and Brain Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

The claustrum is a telencephalic cell group (Fig. 1A, B) possessing widespread reciprocal connections with the neocortex<sup>1-5</sup>. In this regard, it bears a unique and striking resemblance to the thalamus. We have now examined the anatomical ordering of pathways linking the claustrum with sensory areas of the cat neocortex and, in parallel electrophysiological experiments, have studied the functional organization of claustral sensory zones so identified. Our findings indicate that there are discrete visual and somatosensory subdivisions in the claustrum interconnected with the corresponding primary sensory areas of the neocortex and that the respective zones contain orderly retinotopic and somatotopic maps. A third claustral region receiving fibre projections from the auditory cortex in or near area Ep was found to contain neurones responsive to auditory stimulation. We conclude that loops connecting sensory areas of the neocortex with satellite zones in the claustrum contribute to the early processing of exteroceptive information by the forebrain.

Areas 17, 18 and 19 of visual cortex are known to have overlapping fibre connections with a small dorsocaudal sector of the claustrum<sup>6</sup> and the pathway from areas 17 has a rostrocaudal topography<sup>5</sup>. To analyse the claustral origins and terminations of these visual pathways in detail, we carried out neuroanatomical experiments with the tracers horseradish peroxidase<sup>7</sup>

**Fig. 1** A, Representative frontal section through left hemisphere ~2 mm ahead of the caudal tip of the claustrum. The claustrum is set off by cross-hatching. Am: amygdala. Pu: putamen. Th: thalamus. B, Three-dimensional reconstruction of left claustrum as viewed from a point above, behind and lateral to the structure. Total rostrocaudal extent is ~12 mm. Arrow indicates transverse level of section shown in A. C, D, Patterns of tracer labelling in the claustrum elicited by injections of HRP and NY in parts of area 17 representing vertically separated (U = upper, L = lower) and horizontally separated (C = central, P = peripheral) areas in the visual field. Transverse sections are shown at 0.5-mm intervals beginning 0.75 mm ahead of caudal tip (lateral is to the left). Scale bar, 2 mm. In each cat, HRP (25% solution in saline, 0.2  $\mu$ l) and NY (10% suspension in saline, 0.2  $\mu$ l) were injected into separate parts of area 17, with some encroachment into retinotopically overlapping parts of area 18. The brains were fixed by perfusion with 10% formalin, 0.25% glutaraldehyde and 3% sucrose in 0.1 M phosphate buffer and cut at 50  $\mu$ m. Serial sections were processed for HRP by the TMB method<sup>7</sup>. Retrograde and anterograde HRP-labelling was charted under dark- and light-field illumination and nuclei labelled with NY were identified by intense fluorescence exhibited under 360 nm illumination. The part of the area 17 contralateral visual-field map covered by each injection was estimated from the distribution of label in the lateral geniculate body as follows<sup>17</sup>: C, Dark stipple: HRP: vertical -15° to -40°; horizontal 0° to 30°. Light stipple: NY: vertical +5° to 0°; horizontal 0° to 10°. D, Dark stipple: HRP: vertical -5° to 15°; horizontal 0° to 10°. Light stipple: vertical -5° to -20°; horizontal 30° to 60°.

(HRP) and nuclear yellow<sup>8</sup> (NY), and with isotopically labelled amino acids<sup>9</sup>. In 11 cats, distinguishable tracers were deposited in separate cortical sites under electrophysiological guidance. This approach allowed us, in single animals, to compare patterns of claustral uptake elicited by injections in retinotopically identical parts of two areas or in retinotopically distinct parts of the same area. The findings suggest that projections to and from areas 17 and 18 are organized retinotopically and in register, with the upper-to-lower axis of the visual field represented caudorostrally in the claustrum and the central-to-peripheral axis

represented ventrodorsally (Fig. 1C, D). The same pattern is observed in cases (not illustrated) of injections involving area 19. The ventral core of the claustrum, related to the midline of the visual field, is exceptional in having connections with visual cortical areas in both hemispheres (Fig. 2D).

Guided by these anatomical findings, we performed microelectrode-recording experiments in the caudal claustrum of eight cats. Our results demonstrate the existence of a circumscript zone of visually responsive cells closely co-extensive with the region delineated anatomically. Units and unit clusters were exclusively visual, responded best to moving bars and spots and had receptive fields ranging in area from a few degrees square to a few hundred degrees square. Most cells could be driven through either eye and some seemed to be broadly tuned for bar orientation or axis of motion. Responses were weaker and more variable than in area 17 of the same preparation. There was clear evidence for detailed retinotopy in this zone. As shown in Figs 2A, B and 3A, B, receptive fields moved downward systematically as the electrode was moved rostrally and towards the midline as the electrode was advanced ventrally.

To test the generality of the finding of topographic sensory mapping in the claustrum, we studied the slightly more rostral claustral region interconnected with primary somatosensory cortex, SI<sup>10</sup>. Restricted deposits of tracers placed under electrophysiological guidance in parts of SI representing caudal and rostral body parts labelled, respectively, dorsal and ventral sectors in this claustral zone. The pattern of connections was analysed only with respect to the longitudinal body axis because the circumferential axes of the body are not simply represented

in SI<sup>10</sup>. In electrophysiological experiments, we encountered, throughout this region, neurones with large somatosensory receptive fields occupying parts of the contralateral body (Fig. 3). All could be driven effectively by firm pressure or sharp taps and some also responded to light cutaneous stimulation. During downward traverses, receptive fields shifted gradually from the hindparts to the face (Figs 2C, 3C). This pattern of organization, though not noted in previous physiological studies<sup>11</sup>, is in accord with the demonstration of somatotopy based on the anatomy (Fig. 2E).

In contrast to the findings for visual and somatosensory cortex, injections of HRP confined to the primary auditory cortex have not, in our hands, consistently produced labelling in the claustrum (compare with ref. 4). However, injections encroaching on or centred in area Ep of the posterior ectosylvian gyrus, a region of known auditory affiliations<sup>12,13</sup>, have produced anterograde and retrograde labelling of a claustral zone lying beneath the somatosensory division and approximately co-extensive with it rostrocaudally. Guided by this observation, we searched for and found a region of exclusive auditory responsiveness in the claustrum. During downward passes of the electrode, this region typically was encountered within a few 100  $\mu$ m of the most ventral somatosensory activity, and was lost again within 100–200  $\mu$ m (Fig. 3, C11). Cells recorded at this depth characteristically responded to clicks or tone bursts delivered to either ear, as well as to a variety of free-field stimuli. We have not mapped the auditory zone through its full extent.

The connections of the neocortex with the claustrum are organized not only by cortical area but also by cortical layer. In

**Fig. 2** A–C, Transverse sections stained by the Nissl method illustrating vertical electrode penetrations through the claustrum. Along tracks shown in A and B, the units recorded had the visual receptive fields plotted to the left in Fig. 3. C shows, from another experiment, a more rostral track along which units were driven by somatosensory stimuli as plotted to the right in Fig. 3, except for the most ventral unit (C11), which responded to auditory stimulation. Cats were prepared for single-unit recording by standard methods<sup>18</sup> and were maintained under Flaxedil paralysis on N<sub>2</sub>O anaesthesia supplemented with barbiturates. The microelectrode was advanced in 100- $\mu$ m steps and successive recording sites were numbered sequentially beginning at the top of the claustrum. Electrolytic marking lesions (10  $\mu$ m, 10 s, tip negative) were made at A15, B7, C1 and C13. The tracks of A, B and C were placed, respectively, 0.4, 2.4 and 6.0 mm in front of the caudal tip of the claustrum. Scale bar, 1 mm. D, Photomicrograph illustrating intermingled cell populations labelled in the claustrum by HRP injected into the ipsilateral area centralis representation of areas 17 and 18 and NY injected into the homotopic locus in the contralateral hemisphere. From a 50- $\mu$ m frontal section 1.1 mm ahead of the caudal tip of the claustrum and viewed under 360 nm illumination; dark cytoplasmic reaction product indicates HRP labelling and bright nuclear fluorescence indicates NY labelling. Scale bar, 200  $\mu$ m. The most dorsal HRP-positive neurones lie 300  $\mu$ m below the dorsal border of the claustrum. E, Dark-field photomicrograph of a transverse section through the somatosensory claustrum shows the results of a combined electrophysiological-neuroanatomical experiment. As the electrode was lowered along the track marked by the vertical white line, cells with receptive fields containing the hindleg were encountered first (E1–E3), followed by cells with receptive fields restricted to more rostral body parts (E4–E7). Subsequently, HRP was injected under electrophysiological guidance into the area of primary somatosensory cortex (SI) representing the hindleg. The dorsal zone of dust-like reaction product, indicative of HRP transported along corticofugal axons, overlaps closely the stretch of the track (E1–E3) along which hindleg responses were recorded. The track was placed 5.9 mm rostral to the caudal tip of the claustrum and a marking lesion was made at the bottom of the track (E7) (note erythrocytes at the site of the lesion labelled because of their endogenous peroxidase activity). Scale bar, 0.5 mm.

**Fig. 3** Visual and somatosensory receptive fields of selected units recorded along the tracks shown in A, B and C of Fig. 2. The electrode was advanced in 100- $\mu$ m steps and recording sites were numbered consecutively in downward succession from the claustral surface. Visual receptive fields were plotted on a hemispheric screen, here shown in frontal projection with concentric circles representing 45° and 90° isodeviation lines. The pronounced upward progression of fields plotted during track A confirms anatomical evidence (not shown here) indicating that the extreme upper visual periphery is represented ventrocaudally in the claustrum, as in the cortex. The figurine map to the right illustrates the systematic caudorostral progression of receptive fields observed as units recorded at successively deeper sites along track C in the somatosensory claustrum. For clarity, only selected representative somatic fields are shown here. The unit at C11, recorded just below the region of somatic responsiveness, was excited by clicks or tone bursts delivered to either ear.

tree shrew area 17, the claustral projection arises in neurones of layer VI whereas the return pathway terminates in a number of layers including I and IV<sup>5</sup>. We have confirmed and extended these results in the cat, first, by injecting anterograde and retrograde tracers into the caudal claustrum and observing patterns of transported label in area 17, and, second, by comparing the cell populations in area 17 projecting, respectively, to the claustrum and to the lateral geniculate body (LGd). The anterograde results suggest that in the cat the claustrum projects densely to layer I, but there was also heavy labelling of deeper layers, including IV. The retrograde results indicate that the projection to the claustrum arises from cells in layer VI. These cells seem to be distinct from those projecting to the LGd<sup>14</sup>, for in two cases intermingled but separate layer-VI populations were labelled following placement of distinguishable retrograde tracers (NY and HRP) in retinotopically matched parts of the claustrum and the LGd.

The claustrum bears a unique resemblance to the thalamus by virtue of its extensive reciprocal connections with the neocortex. We have extended this parallel by showing that the claustrum, like the thalamus, contains discrete subdivisions that are tightly interlinked with sensory cortex and are organized topographically. However, in lacking major ascending sensory connections, the claustrum fails to share at least the relay functions of the thalamus and seems, in its sensory afference, to be a satellite of the neocortex. This is a rare pattern, a second instance being the almost exclusive dependence of the parabigeminal nucleus on the superior colliculus<sup>15</sup>. Like the sensory divisions of the claustrum, the parabigeminal nucleus is a small cell group receiving a topographic projection from a subset of cells in a much larger structure to which it returns a topographically organized projection<sup>15,16</sup>. Why either cell group should exist as a satellite and not as a set of interneurons within the parent structure is an intriguing question to which no satisfactory answer has been obtained.

We thank Drs H. G. J. M. Kuypers, O. Dann and J. Loewe for fluorescent tracers used in this study. The work was supported

by NIH R01EY02866-02, NIH EY05316-01 and NSF 5T32GM07045.

**Note added in proof:** Since submission of this paper, the existence of retinotopic organization in the claustrum has been reported independently<sup>19</sup>.

## Dorsal column input into the reticular formation

N. A. Salibi\*, N. E. Saadé†, N. R. Banna† & S. J. Jabbur\*‡

\* Department of Physiology, American University of Beirut, Beirut, Lebanon

† Comparative Physiology Laboratory, Faculty of Sciences, Lebanese University, Hadath-Beirut, Lebanon

Somatic sensory information, such as touch, pressure, pain and body position, is conveyed to the mammalian thalamus and ultimately the cerebral cortex along three major ascending pathways in the spinal cord: (1) the dorsal column medial lemniscal (DCML) system, (2) the ventral column (VC) system, including the 'neospinothalamic', 'palaeospinothalamic' and spinothalamic tracts, and (3) the spino-cervico-lemniscal (SCL) system<sup>1,2</sup>. The phylogenetically recent DCML system has been traditionally viewed as an exclusive and homogeneous one-to-one relay of somatic sensory information to the thalamic ventralis posterolateralis nucleus. The emerging evidence, however, shows the gracile and cuneate nuclei as non-homogeneous structures which contain neurones that are subject to many kinds of central and peripheral influences, and which include neurones that do not project to the thalamus<sup>3</sup>. The relation of the ascending spinal pathways to the brain stem reticular formation (RF) is of particular interest in view of the numerous important functions subserved by this region. The spinal input into the RF is generally considered to reach it exclusively through the VC<sup>4</sup>. In view of their intraspinal connections<sup>5–8</sup>, it is difficult to separate and interact the three ascending spinal pathways. We now demonstrate a DCML input into the gigantocellular nucleus (Rgc) of the medial medullary RF in cats, and show inhibitory as well as excitatory interactions between DCML and VC tracts in RF cells. We used a combination of careful spinal surgical lesions aimed at disconnecting the DCML from the other afferent systems and of localized spinal and peripheral stimulations. Persistence of the response of Rgc neurones to DCML stimulation in decerebrate and decerebellate cats rules out the possibility of descending activation via a feedback loop from the cerebral and cerebellar cortices. In view of the possible involvement of Rgc in processing nociceptive input, these findings are of interest to our understanding of the DCML system in somatosensory function and, in particular, pain mechanisms.

‡ To whom correspondence should be addressed.

Experiments were carried out on 17 adult cats, anaesthetized with 30 mg per kg pentobarbitone sodium (9 cats) or 70 mg per kg chloralose (3 cats), or decerebrated just rostral to the superior colliculus following induction of anaesthesia with ether (5 cats). All animals were subsequently paralysed with gallamine triethiodide and artificially respired. Body temperature, blood pressure and end-tidal  $\text{CO}_2$  were maintained within physiological levels. Laminectomy was performed from  $\text{C}_1$  to  $\text{C}_5$  followed by suboccipital craniectomy and bilateral exposure of the sensorimotor cortex. A coaxial electrode was placed stereotactically in the medial lemniscus at coordinates A 5, L 4.5, V 1.8.

In all cats, the cerebellar connections to the brain stem were interrupted and one of two types of spinal lesion was performed. In the first, the 'dorsal-cut' (d-cut) preparation, the dorsal half of the spinal cord was completely severed at the level of  $\text{C}_1$  or  $\text{C}_3$  (in the latter case, the upper three cervical dorsal roots were also cut) or at both levels. The completeness of the cut was tested electrophysiologically. This preparation eliminates DCML and SCL inputs but allows VC inputs to reach RF following peripheral cutaneous stimuli. In the second, the 'ventral-cut' (v-cut) preparation, the entire spinal cord, except for dorsal columns on both sides, was severed at  $\text{C}_1$  or  $\text{C}_3$ . This preparation leaves the dorsal columns (DC) as the sole connection between the periphery and the brain. At the end of each experiment, the cat was perfused with a 10% formaldehyde solution through the aorta. The whole brain (in non-decerebrate cats) and spinal cord were removed and Nissl-stained. All the lesions were later verified for completeness and accuracy. Experiments where histological lesions were imperfect were discarded.

Electrical stimuli were delivered at the rate 0.5–1 Hz to the DC or ventrolateral tracts of VC through stainless steel bipolar electrodes with 1-mm tip separation and to the central footpad of each limb through needle electrodes. Stimuli consisted of single pulses of 0.05–0.1 ms duration. Occasionally, a train of three pulses was delivered to the VC or the paws. The current pulse strength (peak intensities of 0.5–2.5 mA) and the special precautions to insure that the spinal cord stimuli were localized to the stimulated tracts are described elsewhere<sup>9</sup>. Peripheral stimuli would be expected to be carried into the brain along VC tracts in d-cut cats and along DC tracts in v-cut cats.

We studied 160 Rgc units through microelectrodes at coordinates P 3 to 7, L 1.5 and V –7 to –11. Microelectrode recording sites were marked by the electrocoagulation technique. Most (154) of the units were initially isolated after a DC searching stimulus and 6 units after VC stimulation. DCML-activated cells were widely distributed in Rgc and their occurrence correlated

well with the amplitude of the gross potential evoked by DC stimulation. These cells responded to contralateral DC (CDC), ipsilateral medial lemniscal and, most interestingly, to peripheral stimulation in v-cut cats (Fig. 1). The CDC activation pattern consisted of one or more spikes per discharge. Spontaneous activity, when present, was also modified. CDC stimulation (just above  $\text{C}_1$  cut) evoked a response which ranged in latency between 2 and 14 ms. The shorter latency units showed a frequency following up to 50 Hz (but usually less than 25 Hz). Medial lemniscal stimulation was tested in 91 units in non-decerebrate cats, 66 of which responded, usually with latencies and frequency following characteristics similar to those evoked by CDC stimulation.

Of 82 units studied in v-cut cats, most (79 units) responded to DC stimulation and 53 responded to electrical stimulation of the footpads (Fig. 1c, d). The natural receptive fields could be determined in 20 of these cells (18 responded to touch, 2 to hair stimulation). Such fields were usually well defined and circumscribed.

Of the total 160 units studied, 110 were activated through the VC following stimulation of either the VC directly along the ventrolateral tracts or the peripheral paws in d-cut cats. In the latter, unit responses evoked by direct VC stimulation were similar to those evoked by peripheral stimulation, except for slightly shorter latencies. These units were activated by electrical stimuli to all four paws and, in some instances, by acoustic stimuli as well. Some of these units were stimulated or inhibited by noxious pinch at several peripheral sites. Thus, compared with units responding to CDC stimulation in v-cut cats, these units showed more diffuse receptive fields and somewhat longer initial spike latencies.

Interactions between DC and VC inputs on Rgc neurones were studied using conditioning-testing techniques in 79 units discharging to both DC and VC inputs and 32 units discharging to one input only. All (except two) units demonstrated an interaction between the two inputs which took the form of inhibition (48 units) or initial facilitation for 30–40 ms followed by inhibition (61 units). Inhibition lasted up to 200–600 ms.

These results strongly support the existence of an input from the DCML system into the RF which also interacts with the well known VC inputs. We cannot explain the failure of recent physiological studies<sup>10–12</sup> to observe these connections. The neuroanatomical substrate for this DC–RF route also remains unclear except perhaps for the brief description of sparse projections from the DC nuclei into the RF with silver degeneration stains<sup>13–15</sup> or in Golgi-stained serial sections<sup>16</sup>. Similar sparse projections have been described from the dorsal roots (presumably through the DC) to the RF<sup>17</sup>. It is difficult to ascertain whether the dense DC nuclear projection to the inferior olive<sup>18</sup>, which in turn connects reciprocally to the RF<sup>19</sup>, could mediate the DC influences on the RF described here. However, RF projections into DC nuclei have recently been described<sup>20–23</sup>.

The above DC–RF connection could be part of a 'palaeolemniscal' subsystem of the DCML system recently shown to originate from distinct parts of the DC nuclei, to possess a significant number of post-primary DC fibres, and to be characterized by a more diffuse arrangement of neurones with widespread efferents into thalamic (other than VPL) and brain stem areas<sup>24</sup>. The DC–Rgc route and the DC–VC interactions on Rgc neurones described here support the hypothesis, reviewed by Dennis and Melzack<sup>25</sup>, implicating the palaeolemniscal component of the DCML system in pain mechanisms.

This investigation was supported by two grants from the Lebanese National Research Council. We thank Professor P. D. Wall for reading and commenting on the manuscript, and M. Shakarji for technical assistance.

## Adult tissues contain chemo-attractants for vascular endothelial cells

Bert M. Glaser & Patricia A. D'Amore

New blood vessel formation, or angiogenesis, occurs through the migration of endothelial cells in elongated sprouts. These sprouts are directed preferentially towards the inciting stimulus<sup>1-3</sup>. Several studies have demonstrated that certain chemical substances can stimulate angiogenesis<sup>4-7</sup>. In these cases, endothelial cell migration towards the chemical stimulus may be due to a preferential migration of cells from lower to higher concentrations of the mediator. Such concentration gradient-dependent cellular migration has been termed chemotaxis<sup>8</sup>. Using a modification of the Boyden chamber technique<sup>9</sup> to measure chemotaxis *in vitro*, we have now found that extracts of various adult bovine tissues have potent chemotactic activity for vascular endothelial cells. Adult bovine serum lacks similar chemotactic activity.

The blind well Boyden chamber<sup>9</sup>, commonly used for studying chemotaxis, consists of two wells (an upper well and a lower well) separated by a porous membrane. A known concentration of the chemoattractant to be tested is placed in the lower well. The upper well receives a predetermined number of cells and, in some experiments, a known concentration of chemoattractant. The cells we used were fetal bovine aortic endothelial cells, prepared as described previously<sup>7,10</sup>. The cells attach to the upper surface of the membrane, migrate through the pores and then attach to the lower surface of the membrane (Fig. 1). We have found that, unlike some other cell types<sup>11,12</sup>, less than 5% of the vascular endothelial cells detach from the lower surface of the membrane during the experiment. Therefore, the number of cells found on the lower surface of the membrane accurately reflects the number of endothelial cells which have migrated through the pores. The relationship between the number of cells migrating through the porous membrane and the concentration gradient of attractant across the membrane can then be

Fig. 1 Scanning electron micrograph of the lower surface of a porous membrane, showing two successive stages of endothelial cell migration through the membrane. The cell shown in the lower half of the field has extended only a slender cell process to attach to the undersurface of the membrane. The cell in the upper half of the field has extended a large pseudopod through a pore to attach to the undersurface of the membrane.  $\times 4,900$ .

Fig. 2 Effect of bovine retinal extract on vascular endothelial cell migration. Migration is measured using blind well chambers (Neuroprobe, no. 200-312) and polyvinylpyrrolidone-free polycarbonate membranes with 5- $\mu$ m pores (Nucleopore). Retinal extract is prepared by incubating bovine retinas in BSS at room temperature for 3 h (ref. 7). The suspension is centrifuged and the supernatant used immediately or stored at  $-20^{\circ}\text{C}$  (ref. 7). The lower wells receive retinal extract (○), BSS (●) or ABS (△) (Sterile Systems) diluted in minimal essential medium with 10% fetal bovine serum (MEM/10). The upper wells receive 175,000 fetal bovine aortic endothelial cells in 0.8 ml MEM/10 without added retinal extract, salt solution or adult serum. The migration chambers are then incubated at  $37^{\circ}\text{C}$  in 5%  $\text{CO}_2$  with 85% relative humidity for 7 h. The cells on the upper surface of the membranes are then removed with a cotton swab. The cells which have migrated through the membrane on to the lower surface are fixed in a 10% neutral buffered formalin and stained with Wright's stain. Migration is quantified by counting the number of cell nuclei on the lower surface in 14 oil immersion fields (OIF). Each point represents the mean of three experiments  $\pm$  s.e.m. To measure cell attachment to the membranes, each membrane is rinsed in BSS, treated with 0.3 ml of 0.1% trypsin for 5 min, and the trypsin activity quenched by the addition of 0.7 ml MEM/10. The cell number and Trypan blue exclusion are then determined using a haemocytometer. Attachment and viability are measured at hourly intervals during the experiment.

**Table 1** Vascular endothelial cell chemotaxis induced by retinal extract

| % Retinal extract below membrane | % Retinal extract above membrane |          |          |          |
|----------------------------------|----------------------------------|----------|----------|----------|
|                                  | 0                                | 2.5      | 5        | 10       |
| 0                                | 46 (9)                           | 71 (9)   | 56 (4)   | 77 (10)  |
| 2.5                              | 107 (13)                         | 90 (6)   | 89 (5)   | 106 (15) |
| 5                                | 175 (12)                         | 157 (5)  | 124 (3)  | 140 (10) |
| 10                               | 214 (18)                         | 208 (13) | 183 (13) | 142 (13) |

The chemotactic activity of retinal extract was determined using the migration assay as described in Fig. 2 legend, except that various amounts of retinal extract are added to both upper and lower wells to produce a series of concentration gradients across the membranes. Migration is quantified by counting the number of cell nuclei on the lower surface of the membrane in 14 oil immersion fields. Each number represents the mean of three experiments ( $\pm$ s.e.m.). The values in the diagonal, where there is no gradient, show the chemokinetic effects of retinal extract.

determined, thus providing a measure of the chemotactic activity of that substance for vascular endothelial cells *in vitro*.

To investigate the stability of the concentration gradients across the membranes, various amounts of the tricarbocyanine dye indocyanine green (ICG) (maximum final concentration of  $0.5 \mu\text{g ml}^{-1}$ ) were added to the upper and lower wells of the migration chambers. (ICG binds rapidly to serum proteins, mainly albumin (95%)<sup>13</sup>.) The migration assay was then carried out as described in Fig. 2 legend. The concentration of ICG in the upper and lower wells was determined at various times by spectrophotometry. After 4 and 7 h the concentrations varied from their initial values by less than 10% and 20%, respectively. Although we cannot determine the concentration gradient of chemoattractant in the immediate area of the porous membrane, the relative stability of the concentration gradients of ICG-labelled proteins suggests that the initial gradient is a good estimate of the gradient that affects the cells.

Extracts of adult retinas from several mammalian species have been found to be potent stimulators of angiogenesis<sup>7</sup>. We therefore studied their effect on vascular endothelial cell migration to establish that vascular cells could be stimulated to migrate through the porous membranes. The addition of adult bovine retinal extract to the lower well of the migration apparatus results in a marked, dose-dependent increase in the number of endothelial cells moving through the porous membrane as compared with control wells to which balanced salt solution (BSS) is added (Fig. 2). In contrast, adult bovine serum (ABS) does not stimulate endothelial cell migration. The presence of retinal extract, BSS or ABS in the concentrations tested does not affect the rate of endothelial cell attachment or the absolute number of viable cells attaching to the porous membranes (Fig. 2 legend).

These results demonstrate that retinal extract is a potent stimulator of vascular endothelial cell migration but do not indicate whether the effects of the extract are chemotactic or chemokinetic (that is, due to chemically stimulated migration not dependent on concentration gradients). To investigate this,

**Table 2** Vascular endothelial cell chemotaxis induced by various tissue extracts

| % Extract below membrane | % Extract above membrane |         |          |         |
|--------------------------|--------------------------|---------|----------|---------|
|                          | 0                        | 2.5     | 5        | 10      |
| 0                        | 46 (10)                  | 73 (2)  | 91 (12)  | 119 (7) |
| 2.5                      | 159 (17)                 | 154 (3) | 158 (3)  | 139 (6) |
| 5                        | 226 (16)                 | 191 (5) | 153 (3)  | 139 (5) |
| 10                       | 256 (12)                 | 215 (2) | 178 (12) | 149 (8) |

The chemotactic activity of extracts of adult bovine liver, kidney, heart and skeletal muscle was determined as described in Table 1 legend. These extracts were prepared in the same manner as retinal extract (Fig. 2). The chemotactic activity of liver extract is shown above; extracts of the other tissues have similar activity.

we varied the concentration gradient of retinal extract across the membranes and noted the effect on endothelial cell migration. The results shown in Table 1 demonstrate that vascular endothelial cells *in vitro* migrate preferentially from a lower to a higher concentration of bovine retinal extract, and that the extract thus has a chemotactic effect on these cells.

Recent studies on the ability of other adult tissues to stimulate and support new blood vessel growth<sup>7,14-16</sup> have occasionally produced conflicting results. We prepared extracts of adult bovine liver, kidney, heart and skeletal muscle as previously described<sup>7</sup> and found that all have chemotactic activity for vascular endothelial cells *in vitro* (Table 2). These extracts have no effect on the adherence of endothelial cells to the membranes or on endothelial cell viability. The chemotactic activities of all tissue extracts tested are nondialysable (molecular weight cut-off 10,000-12,000), are not retained by an Amicon XM-100 filter (molecular weight cut-off 100,000) and are inactivated by boiling for 2 min.

As vascular endothelial cell migration and chemotaxis seem to be essential for angiogenesis, it is important to study these phenomena in a quantitative *in vitro* system where various parameters can be readily controlled. We have developed a simple, rapid (6-8 h), reproducible and quantitative assay of vascular endothelial cell chemotaxis *in vitro*, and have used it to demonstrate significant chemotactic activity in extracts of various adult bovine tissues. Further study of tissue-derived chemotactic activity should improve our understanding of neo-vascularization. Furthermore, it is reasonable to assume that chemotactic behaviour in endothelial cells has a crucial role in developmental events.

## Leukotrienes are potent constrictors of human bronchi

Sven-Erik Dahlén\*, Per Hedqvist\*, Sven Hammarström† & Bengt Samuelsson†

Departments of \*Physiology and †Chemistry, Karolinska Institutet, Stockholm S-104-01, Sweden

Slow reacting substance of anaphylaxis (SRS-A) is released by various stimuli, including immunological challenge, and has long been considered an important mediator of immediate hypersensitivity reactions, such as bronchoconstriction in allergic asthma<sup>1-3</sup>. Recently, slow reacting substances from several tissues have been identified and characterized as members of a newly discovered group of substances, the leukotrienes<sup>4</sup>. Leukotrienes are generated from arachidonic acid and other polyunsaturated fatty acids in a pathway initially involving a lipoxygenase-catalysed oxygenation at C-5 (Fig. 1). This differs

from the synthesis of prostaglandins and thromboxanes, where the initial transformation of arachidonic acid is catalysed by a cyclo oxygenase (Fig. 1). Recently, leukotriene  $C_4$  ( $LTC_4$ : 5(*S*)-hydroxy, 6(*R*)-*S*- glutathionyl-7,9-*trans*, 11,14-*cis*- eicosatetraenoic acid) and  $D_4$  ( $LTD_4$ : 5(*S*)-hydroxy, 6(*R*)-*S*-cysteinylglycyl-7,9-*trans*, 11,14-*cis*-eicosatetraenoic acid) were found to have biological effects in several bioassay systems, which are strikingly similar to those previously reported for impure extracts of SRS-A<sup>5,6</sup>. Here we report the remarkable contractile activity of both  $LTC_4$  and  $LTD_4$  on isolated human bronchi, which further emphasizes the possibility that leukotrienes are potent mediators of bronchoconstriction in man.

Macroscopically normal parts were selected from human lung parenchyma excised because of carcinoma, and immediately after removal placed in ice-cold Tyrode solution. Bronchi with a diameter of 2–4 mm were cut into helical strips and suspended in a 5-ml organ bath filled with Tyrode solution containing (mM): NaCl 149, KCl 2.7,  $NaHCO_3$  11.9,  $CaCl_2$  1.8,  $MgCl_2$  0.5,  $NaH_2PO_4$  0.4 and glucose 5.5, kept at 37°C gassed with 5%  $CO_2$  in  $O_2$ . Contractions were recorded on a Grass Model 7 Polygraph using an isometric Grass FT 03C force displacement transducer (resting tension 5 mN). Drug concentrations are expressed as final concentration in bath fluid surrounding the tissue. Leukotrienes  $C_4$  and  $D_4$  were generated biosynthetically, as described previously<sup>7–9</sup>.  $LTA_4$  was obtained by hydrolysis of its methyl ester, and was dissolved in ethanol whereas  $LTC_4$  and  $LTD_4$  were dissolved in 0.9% NaCl:ethanol (5:1). Care was taken to avoid ethanol concentrations in the bath above 0.05%, because ethanol can itself act on the preparation.

$LTC_4$  and  $LTD_4$ , as well as histamine, caused dose-dependent and long-lasting contractions of human bronchial strips (Fig. 2). The contraction induced by histamine readily disappeared after changing of the bath fluid, whereas the response to both  $LTC_4$  or  $LTD_4$  vanished only very slowly even after repeated washing. In fact, a contraction obtained by a high dose of  $LTC_4$  (100 nM), although reversible by isoprenaline (1  $\mu$ M), reappeared when added drugs were washed out.

The proposed SRS-A antagonist FPL 55 712 (1–10  $\mu$ M) reversed the contraction induced by  $LTC_4$  or  $LTD_4$ , whereas the

Fig. 2 Contraction responses to histamine (Hi),  $LTC_4$ ,  $LTD_4$  and  $LTA_4$  in isolated human bronchi. Drugs added at arrows, wash indicated by broken curve.

histamine response was largely unaffected (not shown). Blockade of muscarinic and histamine-1 receptors by atropine (1  $\mu$ M) and mepyramine (1  $\mu$ M), respectively, had no effect on the  $LTC_4$ -contraction.

Because repeated administration of leukotrienes seemed to cause tachyphylaxis, we used non-cumulative administration of drugs to assess their potency. The log dose-response curves thus obtained for histamine and  $LTC_4$  almost paralleled and had similar maximal values, but the  $LTC_4$  curve was markedly to the left of histamine. The regression lines calculated from the dose-response relationships of the two compounds showed a 100% increase in resting tension of the preparation ( $ED_{100\%}$ ) obtained with 6.3 nM  $LTC_4$  and 10  $\mu$ M histamine (Fig. 3). This indicates that, on a molar basis,  $LTC_4$  is at least 1,000 times more potent than histamine in causing contraction of isolated human bronchi.

In some experiments, the contractile effect of  $LTC_4$  was compared with that of  $LTD_4$  (Fig. 2). There were no large differences in potency between the two compounds in either the low or high concentration range. However,  $PGF_{2\alpha}$ , recognized as an effective bronchoconstrictor<sup>10</sup>, was always more than 500 times less potent than  $LTC_4$ . The close similarity between  $LTC_4$  and  $LTD_4$  in causing contraction of the human bronchi agrees well with their equipotency as bronchoconstrictors in the guinea pig lung both *in vitro* and *in vivo*<sup>5</sup>, although it has been suggested that  $LTD_4$  is more potent than  $LTC_4$  in the guinea pig parenchymal strip<sup>11</sup>. Whether the observed similarity in potency between  $LTC_4$  and  $LTD_4$  is due to a rapid conversion of administered  $LTC_4$  into  $LTD_4$  by the enzyme  $\gamma$ -glutamyl transpeptidase (GGTP)<sup>8,12</sup>, tissue catabolism of  $LTD_4$ , or a true equipotency as contractile agents on bronchial smooth muscle, remains to be established.

$LTA_4$ , the unstable epoxide intermediate formed from 5-hydroperoxy-6,8,11,14-eicosatetraenoic acid (5-HPETE)<sup>4</sup> (Fig. 1), was less potent than both  $LTC_4$  and  $LTD_4$ , but almost as potent as histamine in causing contraction of the bronchial strip (Fig. 2). The effect of  $LTA_4$  seemed to be more short-lived than that of  $LTC_4$  or  $LTD_4$  and sometimes the contraction faded before washing. This could be due to spontaneous breakdown of  $LTA_4$  in the organ bath or enzymatic transformation of the substance in the tissue.

It has been shown that SRS-A consists of a mixture of leukotrienes<sup>11,13</sup>, with  $LTC_4$  as the primary product, and depending on the type of tissue and experimental conditions, varying amounts of  $LTD_4$ , and other leukotriene metabolites are formed<sup>12,14</sup>. It has not been established whether  $LTC_4$  or  $LTD_4$  is predominantly formed in human lung tissue *in vivo* but both compounds are highly potent bronchoconstrictors. They both increase the vascular permeability in guinea pig skin<sup>5</sup>; thus leukotrienes must seriously be considered as possible pathophysiological agents causing both the bronchospasm and mucosal oedema of bronchial asthma.

The finding that arachidonic acid can be transformed into leukotrienes might explain the failure of aspirin, and other non-steroidal anti-inflammatory drugs, to alleviate allergic

Fig. 1 Conversions of arachidonic acid into oxygenated derivatives.  $LTA_4$ : leukotriene  $A_4$ , etc. (subscript denotes number of double bonds)<sup>17</sup>. 5-HPETE: 5-hydroperoxy-6,8,11,14-eicosatetraenoic acid. GST: glutathione *S*-transferase. GGTP:  $\gamma$ -glutamyl transpeptidase.

**Fig. 3** Contraction responses to histamine (●,  $n = 16$ ) and LTC<sub>4</sub> (□,  $n = 13$ ) plotted on a semilogarithmic scale. Regression lines calculated according to the method of least squares. ED<sub>100%</sub>, dose of agonist increasing tension 100% above resting level (5 mN). Results for 13 strips obtained from eight subjects.

bronchoconstriction, because these drugs block the cyclooxygenase, but not the lipoxygenase<sup>15</sup> (Fig. 1). It is even possible that in 'aspirin-sensitive' asthma, inhibition of the cyclooxygenase by aspirin could contribute to the symptoms by diverting arachidonic acid metabolism into formation of the potent leukotriene bronchoconstrictors, while formation of prostaglandins inhibiting mediator release<sup>16</sup> is decreased. In addition, the ability of LTC<sub>4</sub> and LTD<sub>4</sub> to cause release of the potent bronchoconstrictor and cyclooxygenase product, thromboxane A<sub>2</sub> (Folco *et al.*, personal communication), further illustrates the complex situation concerning the formation of arachidonic acid-derived products with biological effects relevant to bronchial asthma. The interrelationship between prostaglandins, thromboxanes and leukotrienes in immediate hypersensitivity reactions obviously requires further study. The results presented here demonstrate that the leukotrienes C<sub>4</sub> and D<sub>4</sub> could be of considerable importance in the pathophysiology of human asthma.

We thank all personnel at the Department of Thoracic Surgery, Karolinska Sjukhuset, for help in obtaining tissue specimens, and Dr E. J. Corey for providing the methylester of LTA<sub>4</sub>. Certain arenaviruses have become widely recognized as important human pathogens<sup>1-3</sup>, the most notable among these being Lassa virus, the causative agent of Lassa fever<sup>4</sup>. Two other members of the group, Junin and Machupo virus, are the aetiological agents of Argentine and Bolivian haemorrhagic fevers, respectively<sup>2</sup>. All these agents share both morphological features and to varying degrees serological cross-reactivity with other non-pathogenic arenaviruses<sup>3,5,6</sup>. Despite the evident clinical importance of these viruses, work to define their physicochemical structure and to develop rapid and precise diagnostic techniques has been slow. Consequently, the definitive relationships among West African Lassa strains, strains of a related agent from Mozambique and of an Old World arenavirus, lymphocytic choriomeningitis (LCM), have not been established. This problem is of more than simple taxonomic importance in view of the fact that a Mozambique virus strain produced subclinical infection in experimental monkeys which were then resistant to challenge with monkey and human virulent Lassa virus from Sierra Leone<sup>7</sup>. We have explored the use of monoclonal hybridoma antibodies generated against relatively less hazardous arenaviruses to define antigens cross-reactive with the important human pathogens of the group. Here we describe the use of monoclonal antibodies directed against LCM virus to define antigenic specificities shared among LCM, Lassa and Mozambique viruses.

Hybridoma cell lines were generated by fusion of spleen cells from immunized mice with P3 × 63 Ag8 mouse myeloma cells, and selected in hypoxanthine-aminopterin-thymidine (HAT) medium as described elsewhere<sup>8,9</sup>. Immunization of spleen cell donor mice was accomplished by intraperitoneal (i.p.) inoculation of BALB/c mice with 10<sup>4</sup> plaque-forming units of LCM virus (Armstrong Strain, CA 1371) followed by a second inoculation of 3-7 µg of purified LCM virus given intravenously 3 days before fusion. The spleen cells obtained were fused at a ratio of 10 spleen cells per myeloma cell using polyethylene glycol 1000. Cells were placed in microtitre wells in HAT medium, and wells showing growth were screened for antibody to LCM virus by indirect immunofluorescence<sup>10</sup>. Wells showing evidence of specific antibody were cloned by limiting dilution and the resultant clones again screened for specific antibody either by indirect immunofluorescence or by solid-phase radioimmune assay. Final determination of specificity of the cloned antibodies was made by radioimmune precipitation assay

**Table 1** Cross-reactivity of LCMV hybridoma antibodies with Lassa and Mozambique viruses

| Hybridoma antibody | Immunoglobulin isotype | LCMV polypeptide specificity | Indirect immunofluorescence titre ( $\times 10^{-1}$ ) against: |        |            |
|--------------------|------------------------|------------------------------|---|--------|------------|
|                    |                        |                              | LCMV  | Lassa  | Mozambique |
| 1-1-3 (MAF)        | IgG2A                  | NP                           | 12,800  | 200    | 3,200      |
| 24A-21 (MAF)       | IgG2A                  | NP                           | 51,200  | 51,200 | 51,200     |
| 25-39 (MAF)        | IgG2A                  | NP                           | 12,800  | 6,400  | 6,400      |

MAF: mouse ascites fluid; TCF: tissue culture fluid; ND: not done; NP: 63,000 molecular weight nucleocapsid protein of LCM virus; GP-2: 35,000 molecular weight glycoprotein of LCM virus<sup>11</sup>.

as described elsewhere<sup>11</sup>. Ascites fluids were obtained by inoculation of  $5 \times 10^6$  to  $10^7$  hybridoma cells i.p. into pristane-primed BALB/c mice.

Cross-reactivity was assessed by indirect immunofluorescent staining of spot slides of cells infected with Lassa or Mozambique viruses<sup>12</sup>. These slides were prepared in the maximum containment facility at CDC, Atlanta, and were fixed in acetone. Fluorescein isothiocyanate-conjugated goat antibody to mouse IgG was prepared in this laboratory. Infected cells stained with serial twofold dilutions of culture fluid or ascites from individual hybridoma cultures were examined using a Zeiss fluorescence microscope equipped with a 100-W mercury lamp and epilluminator. The results reported are the highest dilution giving positive staining. Controls included LCM virus-infected cell preparations (positive control) as well as uninfected cells. Control hybridoma culture fluids directed against unrelated viral (Pichinde virus, measles) and non-viral antigens (P3  $\times$  63 Ag8 culture fluid) were used.

Forty-six monoclonal antibody-producing hybridoma cell lines with specificity for LCM virus were analysed for cross-reactivity with Lassa and Mozambique viruses. Of these, 9 reacted against virus-specific determinants expressed at the surface of the LCM-infected cell (M. J. B., unpublished observations). Of the remaining 37 antibodies, most recognized determinants on the viral nucleocapsid protein, although some remain uncharacterized.

To assess the fine specificity of these monoclonal antibodies, we reacted each against two strains of LCM virus differing in their pathogenicity for guinea pigs. These viruses, LCMV Armstrong (ARM)<sup>13</sup> strain and LCMV-WE<sup>14</sup> strain, have not been previously observed to differ serologically. When our panel of nine monoclonal antibodies which reacted at the surface of infected cells was tested against target cells infected with either virus, six antibodies were found to be cross-reactive, two defined determinants unique to LCMV-ARM and one reacted only with LCMV-WE. These results are also of interest because of the low pathogenicity of LCMV-ARM in humans when compared with LCMV-WE. Thus, differences in the virus-specific surface antigens, previously unknown using conventional reagents, were resolved. Similar strain-specific antigenic determinants were not observed in the nucleocapsid protein using our panel of reagents, presumably indicating conservation of this viral polypeptide.

Lassa virus had previously been shown to cross-react with LCM virus by complement fixation<sup>1,7,15</sup> and indirect immunofluorescence<sup>16</sup> tests. We therefore assayed target cells infected with Lassa and Mozambique viruses with our panel of monoclonal antibodies directed against LCM virus, to identify cross-reactive determinants. A panel of 46 monoclonal antibodies was screened. The results summarized in Table 1 showed that five cross-reacted with both viruses and a sixth reacted only with Mozambique virus. Cross-reactivity with Lassa virus was limited to antibodies which recognize determinants on the nucleocapsid protein of LCM virus.

Such antibodies, notably 1-1-3 and 24A-21 (Table 1), did not react at 1:10 dilution to any of the antigens prepared with all

eight New World arenaviruses of the Tacaribe antigenic complex. This pattern suggests that Old World and New World arenaviruses have evolved independently over a long period. These antibodies also provide a convenient method for initial screening of candidate Old World arenaviruses.

Of particular interest was antibody 9-7-5, which reacted with the Mozambique agent but not West African Lassa virus. This antibody, which recognizes the GP-2 glycoprotein on LCM virus-infected cells (M.J.B., unpublished observations), thus enables Mozambique strains to be specifically segregated by serological test. In further tests, we found that antibody 9-7-5 reacted with each of nine 'Mozambique' strains recovered from *Mastomys natalensis* rodents in that country and in Zimbabwe, whereas it failed to detect antigens produced by six West African Lassa strains of human and rodent origin obtained from Nigeria, Liberia and Sierra Leone.

Monoclonal antibodies have proved to be useful tools in analysing virus-specific antigens. The present study demonstrates that antibodies raised *in vitro* against LCM virus, the prototype virus of the arenavirus group, can be used to analyse cross-reactive viruses in the group. This ability to raise useful cross-reactive monoclonal antibodies may make it possible to circumvent the need to grow dangerous pathogens such as Lassa virus yet still produce useful and precise clinical reagents. Such reagents would be expected to facilitate the rapid and accurate identification of virus isolates. In particular, the reaction of the anti-glycoprotein monoclonal antibody 9-7-5, which specifically cross-reacts with Mozambique virus but not Lassa virus, suggests that Mozambique virus shares homology in the envelope glycoprotein with LCM virus. We are now expanding our panel of monoclonal reagents both to facilitate the precise identification of clinical isolates and to analyse further the antigenic relatedness among arenaviruses.

## Production of human hybridomas secreting antibodies to measles virus

Carlo M. Croce\*, Alban Linnenbach\*, William Hall†, Zenon Steplewski\* & Hilary Koprowski\*

† Rockefeller University, New York, New York 10021

Monoclonal antibodies against a variety of antigens can be produced using techniques of somatic cell hybridization between cells of rodent myeloma lines and B cells derived from animals immunized against a given antigen<sup>1,2</sup>. However, because the monoclonal antibodies secreted by these hybridomas are of rodent origin, their use in human immunotherapy is limited. Thus the production of B-cell hybrids that secrete human monoclonal antibodies may be of considerable value. We have hybridized a hypoxanthine phosphoribosyl transferase (HPRT)-deficient human B-cell line derived from a patient suffering from multiple myeloma with peripheral lymphocytes obtained from a patient with subacute sclerosing panencephalitis (SSPE). These hybridomas were found to secrete human IgM specific for measles virus nucleocapsids.

As human chromosomes are lost in mouse × human hybridomas<sup>3,4</sup> it is difficult to obtain interspecies hybridomas that secrete human antibodies, because such hybrids must retain both of the two human chromosomes that carry the rearranged genes for the human light and heavy immunoglobulin chains<sup>3,4</sup>. The chromosomal constitution of intraspecific human hybrids is much more stable<sup>5</sup>; therefore we decided to use a HPRT-deficient human B-cell line derived from a patient with multiple myeloma to produce human × human hybridomas. We mutagenized human B-cell line GM 1500 (obtained from the Human Cell Depository, Camden, New Jersey)<sup>3</sup> with ethylmethane sulphonate (EMS) and selected the mutagenized cells in the presence of 30 µg ml<sup>-1</sup> 6-thioguanine. Two independent mutants, GM 1500 6TG-A1 1 and GM 1500 6TG-A1 2, were obtained. They did not express HPRT activity and died in

**Fig. 1** Immunoprecipitation and 10% SDS-polyacrylamide gel electrophoresis of secreted human immunoglobulin chains produced by human hybridomas. Hybridoma cultures were labelled with 100 µCi <sup>3</sup>H-leucine (70 Ci per mmol) per ml for 12 h. The human immunoglobulin chains were immunoprecipitated with rabbit anti-human heavy chain antigen using established procedures<sup>3,4</sup>, then separated by 10% SDS-polyacrylamide gel electrophoresis as described elsewhere<sup>3,4</sup>. Lane 1, immunoprecipitates of the immunoglobulin produced by GM 1500 6TG-A1 2 cells after reaction with an anti-human γ antiserum; lanes 2–6, immunoprecipitates of immunoglobulin chains secreted by human × human hybridomas after reaction with anti-human μ antiserum; lane 7, immunoprecipitate of immunoglobulin chains secreted by hybridoma D3 after reaction with anti-human μ and γ antiserum.

**Fig. 2** Polyacrylamide gel electrophoretic analysis of the measles virus polypeptides precipitated by the various monoclonal antibodies. *a*, Virus polypeptides precipitated by convalescent serum of a patient with atypical measles were used as markers. The polypeptides are as follows: H, the virus haemagglutinin; P, a polypeptide associated with the internal nucleocapsid structure; NP, the major structural polypeptide of the nucleocapsid; F, the polypeptide responsible for cell fusion and haemolytic activities; M, the non-glycosylated membrane polypeptide. Bands 1, 2 and 3 are not unique virus polypeptides, but represent proteolytic cleavage fragments of the NP polypeptide<sup>8</sup>. *b*, Virus polypeptides precipitated by antibody D3. *c*, Polypeptides precipitated by antibody C5. *d*, Culture fluid from the human GM 1500 6TG-A1 2 cell line. Culture fluids of *b*, *c* and *d* were concentrated 20-fold by freeze-drying before use. The procedures used in immunoprecipitation, similar to those described elsewhere<sup>1</sup>, were as follows: lysates of virus-infected CV1 cells labelled with <sup>35</sup>S-methionine were used as antigen. Aliquots (25 µl) were mixed with 100 µl concentrated culture fluid and incubated at 37 °C for 90 min then at 4 °C for 4 h. Rabbit total anti-human antibody (25 µl) was then added and the incubation period repeated. Precipitated polypeptides were collected by centrifugation in an Eppendorf centrifuge for 20 min at 10,000 r.p.m. The visible pellet was resuspended and washed three times. After the final washing, the pellet was suspended in lysis buffer, boiled for 3 min and electrophoresed on a 10% SDS-polyacrylamide gel in conditions described elsewhere<sup>1</sup>. After fluorography, dried gels were exposed to Cronex X-ray film.

**Fig. 3** Lane *a* represents the virus polypeptides precipitated by the same atypical measles serum as in Fig. 2*a*. *b*, Polyacrylamide gel electrophoretic analysis of the measles virus polypeptides precipitated by culture fluid from subclone D3M2. The conditions of the experiments were as described in the legend to Fig. 2, except that culture fluid was unconcentrated.

hypoxanthine-aminopterin-thymidine (HAT)<sup>6</sup> selective medium (data not shown). The mutant cells were found to secrete human IgG ( $\gamma 2$ ,  $\kappa$ ), as did the parental GM 1500 cells (Fig. 1, lane 1)<sup>3</sup>.

Heparinized blood plasma was obtained from a patient suffering from SSPE. This patient was a 19-yr-old female who had first developed SSPE at age 9—the disease lasted for 2 yr, leading ultimately to recovery with the persistence of only some residual symptoms. At the age of 18 yr, she married and became pregnant, then in the fourth month of pregnancy SSPE recurred with great severity and she is now in a chronic vegetative state. Measles virus was isolated from a brain fragment during the first tissue culture. Serum from the patient, diluted 1:10<sup>6</sup>, bound in radioimmunoassay (RIA) with measles-infected target cells. These data, as well as typical histological lesions of the brain, confirmed the clinical diagnosis of SSPE.

Using established procedures<sup>3,4</sup>, we fused 10<sup>7</sup> GM 1500 6TG-A1 2 cells with Ficoll-purified lymphocytes derived from peripheral blood (10 ml) taken from the patient in the presence of polyethylene glycol 1000 (ref. 7). The fused cells were distributed into 24 wells of a Linbro FB-16-24 TC plate in the presence of HAT selective medium. Growth of hybrids was detected in 20 of the 24 wells. These hybrids were propagated in HAT-RPMI 1640 medium and cloned by limiting dilution. Each independent clone (derived from an independent well) was tested for the expression of human immunoglobulin chains and for the ability to immunoprecipitate measles virus proteins<sup>8</sup>.

As shown in Fig. 1, six hybrid clones, including the two that reacted with measles virus (see Fig. 2), expressed the human  $\mu$  chains, as determined by immunoprecipitation of the immunoglobulins secreted by the hybrids with rabbit anti-human  $\mu$  antiserum<sup>3,4</sup>. Some hybridomas also expressed a light chain (L) that migrated differently from the light chain expressed by the GM 1500 line. The clone of the hybridoma illustrated in lane 6 (Fig. 1) lost the ability to produce the light chain expressed by

GM 1500. The hybridoma culture fluid in lane 7 was immunoprecipitated with both anti-human  $\mu$  and anti-human  $\gamma$  chain antisera—the hybrid expressed two heavy chains, the  $\gamma$  chain of the GM 1500 parent and the  $\mu$  chain of the human SSPE B-cell parent.

The specificity of the antibodies for measles virus was determined by immunoprecipitation using methods similar to those described elsewhere<sup>8</sup>. Culture fluids from cultures D3 and C5 only precipitated the virus nucleocapsid polypeptide (NP) and varying amounts of its cleavage fragments (Fig. 2). The antibodies in the culture fluids seemed to be specific for this one polypeptide which is the major polypeptide of the virus nucleocapsid<sup>8</sup>. NP is extremely sensitive to proteolytic cleavage<sup>8</sup>, thus the long incubation periods used in the immunoprecipitation procedure could be partly responsible for the high level of cleavage of the polypeptide. The level of cleavage is particularly evident in Fig. 2*c*. The specificity of the antibodies for NP was confirmed by the demonstration that subclones of hybrid clone D3 could also precipitate this polypeptide (Fig. 3*b*).

These results indicate that it is possible to obtain human B-cell hybrids which continuously secrete human antibodies, particularly antibodies specific for a human pathogenic virus. The availability of a human continuous B-cell line with appropriate drug resistance markers represents a breakthrough in work towards the possible application of this technology to human immunotherapy. In addition, lymphocytes from patients with human autoimmune diseases such as myasthenia gravis and Graves' disease could be fused with human B-cell lines to produce hybridomas that secrete the autoantibodies responsible for the disease. Once such monoclonal autoantibodies are available, the production of anti-autoantibodies could provide a cure for patients with autoimmune diseases.

## Surface phenotypes in T-cell leukaemia are determined by oncogenic retroviruses

Christoph C. Zielinski, Samuel D. Waksal, Laurence D. Tempelis, Raman H. Khirany & Robert S. Schwartz

Departments of Medicine and Pathology and the Tufts Cancer Research Center, Tufts University School of Medicine, Boston, Massachusetts 02111

Spontaneous thymic leukaemia in experimental mice is the result of a complex series of genetically controlled events<sup>1</sup>. An important step in this process involves the production by thymocytes of recombinant polytropic retroviruses (MCF viruses)<sup>2,3</sup>. These leukaemogenic agents arise by recombination of genes from the *env* regions of endogenous precursor viruses<sup>4,5</sup>. Sequences in these regions encode the envelope glycoprotein gp70 (ref. 6). Thus far, each cloned isolate of recombinant virus from AKR and HRS/J mice has been found to possess unique oligonucleotide sequences in its *env* region, as well as clone-specific peptides in its gp70 (refs 7, 8). Therefore, the polytropic viruses of these leukaemia-susceptible mice are

extremely diverse. These findings suggest that random recombination of *env* genes gives rise to leukaemogenic polytropic viruses. McGrath and Weissman<sup>9</sup> have proposed that thymocytes with cell surface receptors for the gp70 of a particular leukaemogenic virus are the target cells for malignant transformation by that specific virus. In view of the diversity of polytropic viral gp70, their hypothesis would predict extensive phenotypic diversity among spontaneous thymic leukaemias. In contrast, leukaemias induced by a particular leukaemogenic recombinant virus would always have the same phenotype. Here we verify these predictions experimentally.

We studied thymomas that arose spontaneously in HRS/J mice, or that were induced in HRS/J or CBA/J mice by neonatal inoculation of cloned polytropic viruses of HRS/J origin<sup>8</sup>. The surface phenotypes of these tumours were characterized by fluorescent staining of the cells with monoclonal antisera and other reagents, followed by analyses on a fluorescence-activated cell sorter (FACS IV, Becton Dickinson). The surface phenotypes of thymocytes obtained from normal HRS/J and CBA/J mice were also studied with these reagents.

The results obtained with normal thymocytes were similar to those already published<sup>10</sup>, that is, consistently high Thy-1, low H-2K<sup>k</sup> and Ia<sup>k</sup>, and consistently high Lyt-1 and Lyt-2 (Table 1). The percentage of cells that stained with fluorescein isothiocyanate (FITC)-conjugated peanut agglutinin (PNA), a marker of immature thymocytes<sup>11</sup>, was high in all cases. The expression of murine leukaemia virus (MuLV) antigen was low except in old (40-week) HRS/J mice, in which an increase in this antigen is expected<sup>3</sup>.

In comparison, the surface phenotypes of thymocytes from eight spontaneous HRS/J thymomas had no consistent pattern. The thymic tumours were taken from mice that were chosen at random from our animal colony. The sole criterion for the selection was clinical evidence of a tumour. Figure 1 shows that each tumour had a distinctive phenotype, although several features were shared by all of them. All tumours expressed Thy-1.2, although in two cases (*d* and *h*) the percentage of thymocytes that were positive for this marker was lower than in the other six. Moreover, all the neoplasms contained a high percentage of thymocytes that expressed MuLV antigen. All the

**Fig. 1** Thymocyte surface markers of randomly selected spontaneously occurring thymomas in HRS/J mice. All reagents and techniques were the same as for experiments in Table 1. *a*, Thy-1.2; H-2, H-2K<sup>k</sup>; Ia, Ia<sup>k</sup>; Ly1, Lyt-1; Ly2, Lyt-2. Note that each tumour has a distinctive phenotype.

thymomas were low in Ia<sup>k</sup>, which may be characteristic of the HRS/J strain because thymomas from AKR mice express increased amounts of this antigen<sup>12</sup>. Other surface markers (H-2K<sup>k</sup>, Lyt-1, Lyt-2) and the percentage of cells with receptors for PNA varied independently.

The phenotypes of thymomas that were induced by cloned isolates of two HRS/J polytropic viruses (PTV 1 and PTV 2) were examined next. These viruses have been characterized biochemically and each has distinctive oligonucleotides in the *env* region as well as distinctive gp70 peptides<sup>8</sup>. They are highly thymotropic and leukaemogenic in both HRS/J and CBA/J mice<sup>8</sup>. The surface phenotypes of thymomas induced by injection of neonatal mice with PTV 1 or PTV 2 are shown in Table 2. Each cloned virus regularly produced thymomas with phenotypes characteristic of that particular clone. Thus, the neoplasms induced by PTV 1 were low in Thy-1.2, high in H-2K<sup>k</sup>, increased in Ia<sup>k</sup>, high in Lyt-1 and low in Lyt-2. Expression of MuLV by these cells was always high. The percentage of thymocytes with receptors for PNA varied; four thymomas had many and four had few PNA<sup>+</sup> cells. In contrast, PTV 2 induced the development of malignant thymocytes with high expression of Thy-1.2, H-2K<sup>k</sup>, and Lyt-1, whereas the expression of Lyt-2 and Ia<sup>k</sup> was low. MuLV antigen was again expressed by a high percentage of cells. PNA receptor-bearing thymocytes were low in four of five cases. The surface phenotypes of leukaemic cells induced by PTV-1 were similar in CBA, HRS/J and (CBA × HRS/J)<sub>F1</sub> recipients.

These results demonstrate that the surface phenotypes of spontaneously occurring thymomas are apparently random, whereas the phenotypes of thymomas induced by cloned leukaemogenic viruses are predictable and characteristic of a given clone. The PTV 1- and PTV 2-induced leukaemias produce the specific recombinant virus which induced them<sup>8</sup>, so it is unlikely that a new recombinant virus caused these leukaemias. Pepersack *et al.*<sup>13</sup> found phenotypic heterogeneity among thymomas induced by Moloney leukaemia virus. Stocks of this agent contain recombinant viruses<sup>14</sup> which might vary

**Table 1** Expression of cell surface markers and MuLV antigen by normal CBA/J and HRS/J mice of different ages

Suspensions of thymocytes were prepared in phosphate-buffered saline (PBS) supplemented with 5% heat-inactivated fetal calf serum (iFCS) and 0.1% sodium azide.  $1 \times 10^6$  thymocytes were incubated with the following monoclonal antisera for 30 min on ice: anti-Thy-1.2 (NEN, dilution 1:1,000), biotinylated anti-H-2K<sup>k</sup> (1:50) and anti-Ia<sup>k</sup> (1:50), directly fluoresceinated anti-Lyt-1 and -Lyt-2 (Becton-Dickinson); both at a dilution of 3  $\mu$ l antiserum per 100  $\mu$ l diluent. Also used were FITC-PNA (Pharmindustrial, 1:50), and FITC-goat antiserum prepared against Tween-ether disrupted Moloney MuLV (1:1,000). The cells were washed through FCS and incubated, when necessary, with the appropriate second-step reagent—FITC-rabbit anti-mouse immunoglobulin (1:40) or fluorescein-avidin D (Vector Laboratories, 1:50) for another 30 min on ice. The percentages of fluorescent cells were determined and recorded on a FACS.

\* Percentage of fluorescent cells.

from one preparation to another. Studies in AKR/J mice also indicate heterogeneity of spontaneous thymomas<sup>15-17</sup>. Thus, these tumours may be considered as an example of genetically determined neoplasms with a randomly specified phenotype. The diverse phenotypic patterns of these spontaneous leukaemias are consistent with the concept that the causative leukaemogenic viruses arise by random genetic recombination<sup>18</sup>.

The results with cloned viruses demonstrate the induction of neoplasms with virus-specific phenotypes. The mechanism whereby cloned viruses induce leukaemias with a specific phenotype is unknown, but a reasonable conjecture is that this process is related to gp70 because the only major difference between PTV 1 and PTV 2 is in the structure of this glycoprotein<sup>8</sup>. Elder *et al.*<sup>18</sup> have proposed that gp70 may be a transforming protein. We think it unlikely that gp70 contains the information that would be required to specify the distinctive and characteristic leukaemia cell phenotypes we observed. Alternatively, the type of cell that is programmed to undergo transformation by a given retrovirus might be selected by the fortuitous affinity of its receptor for the gp70 of that virus. This hypothesis predicts that certain recombinant retroviruses will not be leukaemogenic because their gp70 cannot bind with sufficient affinity to the receptor of any thymocyte. Moreover, genetic variants of these receptors would explain why a particular recombinant virus is leukaemogenic in some inbred strains of mice, but not in others<sup>7,8</sup>. McGrath and Weissman<sup>9</sup> have argued that recombinant viral gp70 acts via such receptors to stimulate thymocytes immunologically. This persistent immunological stimulation, they propose, leads to malignant transformation of the cell. Their concept implies that the receptor for gp70 is antigen-specific and encoded by V<sub>H</sub> genes. Whereas experimental evidence supports the idea that persistent immunological stimulation can lead to lymphoid malignancy<sup>19</sup>, the receptors being discussed need not have an immunological function. These hypothetical receptors may act in leukaemogenesis simply as points of attachment and penetration by the leukaemogenic agent. If the thymomas we studied represent neoplastic counterparts of various stages of thymocyte differentiation, then the receptors may be differentiation structures on the cell surface rather than antigen-specific receptors.

**Table 2** Surface phenotypes of thymic tumours that developed after intraperitoneal injection of newborn mice with recombinant viruses PTV 1 and PTV 2

| Strain                    | Thy-1.2* | H-2K <sup>k</sup> | Ia <sup>k</sup> | Lyt-1 | Lyt-2 | PNA  | MuLV |
|---------------------------|----------|-------------------|-----------------|-------|-------|------|------|
| <i>a</i> PTV 1            |          |                   |                 |       |       |      |      |

| (CBA × HRS)F <sub>1</sub> | 75.0     | 96.0              | 9.0             | 94.6  | 19.6  | 19.6 | 70.0 |
| <i>b</i> PTV 2            |          |                   |                 |       |       |      |      |
| CBA                       | 98.5     | 76.2              | 27.1            | 89.0  | 25.9  | 9.1  | 96.7 |
| (CBA × HRS)               | 98.4     | 78.4              | 3.0             | 88.9  | 4.2   | 26.9 | 83.6 |
| (CBA × HRS)F <sub>1</sub> | 98.6     | 74.9              | 2.0             | 84.0  | 1.9   | 19.0 | 60.3 |
| (CBA × HRS)F <sub>1</sub> | 95.0     | 87.0              | 6.6             | 90.0  | 9.0   | 84.1 | 93.1 |
| (CBA × HRS)F <sub>1</sub> | 99.1     | 65.3              | 1.5             | 95.5  | 3.5   | 7.4  | 71.5 |

In the group injected with PTV 1 were two CBA, three HRS/J and three (CBA × HRS)F<sub>1</sub> mice (the latter were bred in our animal facility), and in the group injected with PTV 2 were one CBA and four (CBA × HRS)F<sub>1</sub> mice. The viruses were isolated, cloned and characterized according to previously described methods<sup>8</sup>. The latent period between virus injection and the occurrence of thymoma, and the incidence of thymomas did not differ from previous observations<sup>8</sup>. The dose of virus administered to the mice was about  $1 \times 10^5$  focus-forming units. All reagents and techniques were the same as for experiments in Table 1.

\* Percentage of fluorescent cells.

We cannot exclude the possibility that the clones of viruses we studied possess a relevant transforming function that has not been revealed by the previous biochemical analyses of their genomes and major structural proteins. With certain oncogenic avian retroviruses, for example, transforming genes that are specific for certain types of haematopoietic cells have been demonstrated<sup>20</sup>. Clarification of the mechanisms whereby cloned recombinant retroviruses induce characteristic clones of leukaemic cells is therefore in progress. Finally, note that the diversity of cell-surface phenotypes in mouse T-cell leukaemias of viral aetiology, as shown here, resembles a similar heterogeneity in human T-cell leukaemia<sup>21</sup>.

This work was supported in part by grants CA24530 and CA09351 and contract N-01CB-74150. C.C.Z. is on leave from the II Department of Medicine, University of Vienna; S.D.W. is a scholar of the Leukaemia Society of America; L.D.T. is a Damon Runyon-Walter Winchell Cancer Fund Fellow. The authors thank Ms Nancy Bond and Mr Joseph Gabriels for technical assistance. FITC-goat antiserum against Moloney MuLV was supplied by Dr J. Gruber; FITC-rabbit anti-mouse immunoglobulin was a gift from Dr R. Stout.

## Is myosin in the cochlea a basis for active motility?

J. C. Macartney\*, S. D. Comis & J. O. Pickles

Department of Pathology\* and Neurocommunications Research Unit, Birmingham University, Birmingham B15 2TJ, UK

**Recent evidence suggests that the stereocilia of cochlear hair cells contain actin filaments<sup>1-3</sup>. The experiments reported here demonstrate the presence of myosin, suggesting that the mechanical properties of the hair cells may be actively modifiable by actin-myosin interactions as in muscle cells.**

Myosin was detected in the hair cells of the guinea pig cochlea by indirect immunofluorescence using an antiserum raised against human smooth muscle myosin<sup>4</sup>. Immunofluorescence was visible in very specific areas of the organ of Corti. The stereocilia fluoresced strongly along their length (Fig. 1a). It is possible that the bright spots of fluorescence seen in one row of stereocilia in Fig. 1a indicate a concentration of myosin near the roots of the stereocilia, perhaps due to the many rows of short

**Fig. 1** Anti-myosin immunofluorescence (a), and control section using myosin-absorbed antiserum (b) in the outer hair cells of the guinea pig cochlea, seen from above ( $\times 512$ ). The stereocilia of two rows of outer hair cells are in focus at different depths (white arrows, a). Fluorescence is also seen in the apical ends of the supporting cells, in between the hair cells (S). Guinea pig cochleas were fixed briefly in buffered formalin glutaraldehyde<sup>9</sup> and the organ of Corti rapidly dissected out and washed in tris saline buffer (pH 7.6). The intact organs of Corti were fixed in cold acetone ( $-10^{\circ}\text{C}$ ) for 10 min followed by brief air drying and further washing in buffer. Following removal of the buffer the organs of Corti were incubated in a rabbit antiserum raised against smooth muscle myosin<sup>4</sup> diluted 1:20 with tris saline buffer for 60 min, followed by washing in three changes of buffer. The second stage antiserum was a fluorescein-labelled swine anti-rabbit immunoglobulin (Dako-Immunoglobulins 52190) diluted 1:20 in buffer. After washing the specimens were orientated and mounted in glycerol-phosphate buffered saline. They were viewed using a Leitz SM-Lux microscope fitted with a fluorescence vertical illuminator for incident light excitation. Controls included the use of preimmune rabbit serum and myosin-absorbed antiserum in place of the first stage anti-myosin serum.

stereocilia. A similar pattern of fluorescence was seen in inner and outer hair cells. In transverse sections faint immunofluorescence was also seen in the cuticular plate at the apex of the hair cells. Therefore in contrast to the microvilli of the intestinal brush border, most of the immunofluorescence was associated with the cilia rather than any terminal web. It is possible that actin-myosin interactions in such areas could lead to a shortening or a change in stiffness of the stereocilia. Although there is little information on the amount of movement possible, the results of Tilney *et al.*<sup>2</sup> strongly suggest that it may be limited, perhaps due to the large numbers of cross-bridges between the actin filaments<sup>3</sup>. In both transverse and surface preparations immunofluorescence was also visible in the supporting cells between the apical ends of the hair cells (Fig. 1a). It is very unlikely that such structures deform, even passively, thus although these experiments indicate that the molecular basis of actin-myosin interactions exists in the cochlea, they do not indicate that motility must necessarily occur.

These results have the following implications: (1) it has been suggested that the cochlear transducer can produce sound<sup>5</sup>, which may be the result of actin-myosin motility; (2) the changes in the mechanical properties of the cochlea seen after death<sup>6</sup> or the loss of rigidity of the stereocilia, which is an early sign of sound-induced damage<sup>7</sup>, may result from changes in the actin-

myosin linkage; (3) similarly, in physiological conditions the stereocilia may not be as stiff as demonstrated by Flock<sup>1</sup> in the excised organ; (4)  $\text{Ca}^{2+}$ , which is essential for the transduction process<sup>8</sup>, may enter the stereocilia as a result of sound stimulation and so affect the mechanical properties of the hair cells; (5) the nonlinear growth of basilar membrane movement with stimulus intensity<sup>6</sup> may be due to the progressive activation of the actin-myosin linkage as a result of sound stimulation; and (6) the fibres of the olivocochlear bundle may affect the mechanical properties of the hair cells by altering the actin-myosin linkage, perhaps as a result of changed  $\text{Ca}^{2+}$  influx.

## $\text{Ca}^{2+}$ -activated ATPase and ATP-dependent calmodulin-stimulated $\text{Ca}^{2+}$ transport in islet cell plasma membrane

Harrihar A. Pershadsingh\*, Michael L. McDaniel, Michael Landt, Cheryl G. Bry, Paul E. Lacy & Jay M. McDonald

Division of Laboratory Medicine, Departments of Pathology and Medicine, Washington University School of Medicine, St Louis, Missouri 63110

Calcium is known to play an essential part in the regulation of insulin secretion in the pancreatic  $\beta$  cell<sup>1,2</sup>. Calcium influx/efflux studies indicate that glucose promotes an accumulation of calcium by the  $\beta$  cell<sup>2</sup>. However, interpretation of such data is particularly difficult due to the complex compartmentalization of calcium within the cell. Although indirect evidence using chlorotetracycline suggests that control of calcium homeostasis at the plasma membrane may be central to insulin secretion<sup>3</sup>, the mechanism by which secretagogues influence the handling of calcium remains unknown. Despite its continuous diffusive entry, intracellular calcium is maintained in the submicromolar range<sup>4,5</sup> by energy-dependent mechanisms<sup>5-9</sup>. One such process which has been well characterized in erythrocytes is a plasma membrane calcium extrusion pump whose enzymatic basis is a high affinity ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase<sup>9</sup>. A similar mechanism<sup>10,11</sup> regulated by insulin<sup>12,13</sup> has recently been identified in adipocyte plasma membranes. We report here the presence of a high affinity ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase and ATP-dependent calmodulin-stimulated calcium transport system in rat pancreatic islet cell plasma membranes<sup>14</sup>.

Calcium-stimulated ATPase activity was demonstrated in the plasma-membrane enriched fraction from pancreatic islets. The dependence of ATPase activity on calcium concentration revealed the presence of two saturable components similar to those observed in erythrocyte<sup>15</sup> and adipocyte<sup>10</sup> plasma membranes. One had a high affinity for calcium, designated ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase, and achieved saturation at submicro-

\* Present address: University of Missouri-Columbia, School of Medicine, Columbia, Missouri 65212.

**Fig. 1** Calcium dependence of the high affinity ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase in pancreatic islet cell plasma membranes. Islets were isolated from male Sprague-Dawley rats by the method of Lacy and Kostianovsky<sup>37</sup> and the plasma membrane-enriched fraction (band I) was obtained by the method of Naber *et al.*<sup>20,43</sup> with the modification that EDTA was omitted from the homogenization and fractionation buffers. Omission of EDTA does not modify the distribution of organelles among the subcellular fractions<sup>20,43</sup>. The plasma membranes were frozen immediately and were used within 2 days of storage at  $-70^\circ\text{C}$ . ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase activity was quantitated by monitoring the release of  $^{32}\text{P}_i$  from  $[\gamma\text{-}^{32}\text{P}]\text{ATP}$  and is expressed as nmol  $\text{P}_i$  per mg protein per min (ref. 38). Protein was determined as described elsewhere<sup>39</sup>. The assay medium contained 1–2  $\mu\text{g}$  protein per ml with 2 mM EGTA, 1.4–2 mM  $\text{CaCl}_2$  (equivalent to 0.035–2.7  $\mu\text{M}$  free  $\text{Ca}^{2+}$ ), 1–2  $\mu\text{Ci}$   $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ , 0.25 mM ATP (Tris salt), 20 mM  $\text{Na}_2\text{S}_2\text{O}_8$  and 10 mM Tris-PIPES, pH 7.5 at  $37^\circ\text{C}$ . The incubation volume was 1.0 ml. Reaction times were 30 or 60 min. The ATPase reaction rates were linear over the assay period and directly proportional to the amount of tissue added. The amount of ATP hydrolysed was always less than 5% of the total ATP present over the incubation period. Calcium-stimulated activity was determined by subtracting values obtained with chelator alone (background activity) from those obtained with calcium plus chelator. The background ATPase was  $18 \pm 4\%$  ( $n=6$ ) of the maximum velocity of the high affinity ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase. Total endogenous calcium and magnesium in the assay medium were 2.0–2.5 and 8.5–9.0  $\mu\text{M}$ , respectively, as measured by atomic absorption spectroscopy. Each point represents the mean  $\pm$  s.e.m. of triplicate determinations. The inset represents a double-reciprocal plot of the data. Free calcium was calculated using an apparent  $\text{Ca}$ -EGTA association constant of  $10^{7.832} \text{ M}^{-1}$  which was determined for pH 7.5 as described by Portzehl *et al.*<sup>4</sup>. The high affinity ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase was studied at free calcium concentrations  $< 2.7 \mu\text{M}$ —in these conditions ATP has a negligible effect on free calcium in a  $\text{Ca}$ -EGTA buffer system because the apparent  $\text{Ca}$ -ATP association constant ( $10^{3.390} \text{ M}^{-1}$  at pH 7.5) is four orders of magnitude less than that of  $\text{Ca}$ -EGTA. All cation-ligand association constants were obtained from Sillén and Martell<sup>24</sup>.

molar concentrations of free calcium (Fig. 1). Data from five separate preparations yielded a  $K_m$  of  $0.093 \pm 0.010 \mu\text{M}$  free calcium and a Hill coefficient of  $1.5 \pm 0.2$ , both similar to values obtained for erythrocyte<sup>16</sup> and adipocyte<sup>10</sup> plasma membranes. The value of  $V_{\text{max}}$  was  $54.8 \pm 10.1$  nmol of  $\text{P}_i$  released per mg protein per min. The second saturable component which was observed above 10  $\mu\text{M}$  had a comparatively low affinity for free calcium (data not shown).

It is important to demonstrate that the ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase reported here originates from the plasma membrane, because the endoplasmic reticulum of other tissues (and therefore probably the  $\beta$  cell) has a high affinity ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase<sup>17,18</sup> which also drives a calcium pump<sup>18,19</sup>. Three lines of evidence support a plasma membrane location: first, the distribution of the high affinity ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase amongst the four islet-

cell subcellular fractions was shown to parallel directly the distribution of the plasma membrane-specific marker enzyme 5'-nucleotidase with a highly significant degree of correlation (Fig. 2). Second, the ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase activity was inversely related to the distribution of NADH cytochrome *c* reductase (an endoplasmic reticulum-specific marker enzyme) amongst the four subcellular fractions<sup>20,43</sup> and third, both endoplasmic<sup>17</sup> and sarcoplasmic<sup>21</sup> reticulum ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPases from other cells are strongly stimulated by potassium ( $K_m = 10 \text{ mM}$ ), whereas the ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase reported here was slightly inhibited ( $17 \pm 5\%$ ,  $n=3$ ) by 20 mM potassium. Also, as in the erythrocyte<sup>9</sup> and adipocyte<sup>10</sup>, 0.8 mM ouabain had no effect on the ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase.

A calcium-activated ATPase has been identified in subcellular fractions from mouse pancreatic islets by Formby *et al.*<sup>22</sup>. They reported a high affinity activity ( $K_m = 0.18 \mu\text{M}$ ) which seems similar to the high affinity enzyme reported here. However, there is no reason to believe that their high affinity activity represents a plasma membrane enzyme because it is detectable in all subcellular fractions. Indeed, the authors suggested that mitochondria and secretory granules were mostly responsible for their high affinity  $\text{Ca}^{2+}$ -ATPase<sup>22</sup>, but it is possible that it originated from a plasma membrane contamination of the subcellular fractions. We also observed a small inhibitory effect ( $17 \pm 6\%$ ,  $n=3$ ) of sodium (20 mM  $\text{NaCl}$ ) similar to that observed by Formby *et al.*<sup>22</sup> at high ATP concentration. In these experiments 1 mM dicyclohexylcarbodiimide instead of 20 mM sodium azide was used to block the mitochondrial ATPase<sup>23</sup>.

Although magnesium *per se* was not added to the assay medium, it seemed to be necessary for activity, a requirement apparently common to all ion-transporting enzymes. This was shown using the chelator, cyclohexane-1,2-diamine- $N,N,N',N'$ -tetraacetic acid (CDTA, Sigma) which has high affinities for calcium and magnesium whereas EGTA has a high affinity for calcium alone<sup>24</sup>. In the  $\text{Ca}^{2+}$ -CDTA buffer system,  $>99\%$  of the magnesium present in the assay medium (8.5–9.0  $\mu\text{M}$  as measured by atomic absorption spectroscopy) was complexed. When free calcium was maintained at 0.283  $\mu\text{M}$

**Fig. 2** Distribution of the high affinity ( $\text{Ca}^{2+} + \text{Mg}^{2+}$ )ATPase relative to 5'-nucleotidase amongst pancreatic islet subcellular fractions. The plasma membrane-specific marker enzyme, 5'-nucleotidase<sup>40</sup>, was assayed by the method of Avruch and Wallach<sup>41</sup>. Bands I, II, III and IV as designated by Naber *et al.*<sup>20,43</sup> are shown. Free  $[\text{Ca}^{2+}] = 0.283 \mu\text{M}$ . Other assay conditions were as described in Fig. 1 legend. Each point represents the mean  $\pm$  s.e.m. of triplicate determinations for both enzyme activities. Band I, which had the highest activities of both enzymes, was the plasma membrane-enriched fraction used throughout these studies.

using this system, 98% of the  $(\text{Ca}^{2+} + \text{Mg}^{2+})\text{ATPase}$  activity was lost as compared with the activity obtained in a  $\text{Ca}^{2+}$ -EGTA buffer at the same free calcium concentration. Therefore, like the adipocyte enzyme<sup>10</sup>, both calcium and magnesium seem to be required simultaneously for high affinity  $(\text{Ca}^{2+} + \text{Mg}^{2+})\text{ATPase}$  activity. Calcium or magnesium alone cannot produce significant ATPase activity below 10  $\mu\text{M}$ .

$(\text{Ca}^{2+} + \text{Mg}^{2+})\text{ATPase}$  activity gave a complex relationship with varying ATP concentration. Two apparent saturable components with low ( $K_{0.5} = 2.1 \mu\text{M}$ ) and high ( $K_{0.5} = 70 \mu\text{M}$ ) affinities were observed, and were obtained by fitting the Hill equation to the data using the computer program developed by Atkins<sup>25</sup>. (The estimated  $V_{\text{max}}$  for the high affinity component was subtracted from the total activity to obtain data for the low affinity component.) Similar observations have been reported for the high affinity  $(\text{Ca}^{2+} + \text{Mg}^{2+})\text{ATPases}$  of erythrocyte<sup>26,27</sup> and adipocyte<sup>10</sup> plasma membranes.

**Fig. 3** Calmodulin stimulation of ATP-dependent calcium uptake in pancreatic islet cell plasma membranes. Transport was assayed as uptake of  $^{45}\text{Ca}^{2+}$  from a medium containing: 200 mM sucrose, 20 mM  $\text{Na}_2\text{S}_2\text{O}_8$ , 2.5 mM  $\text{MgCl}_2$ , 1.5 mM  $\text{Na}_2\text{ATP}$ , 10 mM Tris-oxalate, 2 mM Tris-EGTA, 1.8 mM  $\text{CaCl}_2$  ( $0.134 \mu\text{M}$  free  $[\text{Ca}^{2+}]$ ), 4–8  $\mu\text{Ci}$   $^{45}\text{CaCl}_2$  and 10 mM Tris-PIPES, pH 7.5 at 37 °C. Magnesium (2 mM) was added to the transport assay medium because it seems to be necessary for ATP-coupled calcium transport<sup>27</sup>. The reaction was initiated by addition of 10–15  $\mu\text{g}$  tissue and incubated for 30 min at 37 °C. The incubation volume was 0.5 ml and the reaction was terminated by rapid filtration of a 0.4-ml aliquot on 0.45- $\mu\text{m}$  Millipore HAWP filters and washed with 30 volumes of isotonic sucrose. Calcium uptake is shown in the absence (far left) and presence of ATP (middle) and with ATP plus calmodulin (far right). Uptake was not linear with time but was directly proportional to the amount of tissue added and is reported as the level attained after 30 min. The presence of ATP and/or calmodulin did not affect the amount of radioactivity bound to the filters. Furthermore, calmodulin did not affect the amount of  $^{45}\text{Ca}^{2+}$  associated with the membranes in the absence of ATP. The data represent results from four separate experiments and are presented as the mean  $\pm$  s.e.m. Each symbol type represents a different preparation. Purified calmodulin was prepared from Sprague-Dawley rat brains by a previously described method<sup>42</sup> and was added to a final concentration of 43 nmol ( $0.72 \mu\text{g ml}^{-1}$ ) assuming a molecular weight of 16,723 (ref. 36). Purity of the calmodulin preparation was established by resolution into a single homogeneous band by SDS-polyacrylamide gel electrophoresis. The ability to stimulate calmodulin-dependent cyclic nucleotide phosphodiesterase and erythrocyte plasma membrane  $(\text{Ca}^{2+} + \text{Mg}^{2+})\text{ATPase}$  were the criteria used to establish the protein's identity<sup>36</sup>. The preparations used in transport experiments contained EDTA in the homogenization buffers. The chelator was required during fractionation to dissociate endogenous calmodulin from the membranes<sup>35</sup>.

To ascertain whether or not the high-affinity plasma membrane  $(\text{Ca}^{2+} + \text{Mg}^{2+})\text{ATPase}$  served as the enzymatic basis of an active transport system, we assayed the preparation for  $^{45}\text{Ca}^{2+}$  transport. ATP-dependent uptake was observed in the islet cell plasma membranes (Fig. 3) and seems to represent accumulation of calcium in vesicles spontaneously formed during fractionation. The ATP-dependent component does not seem to represent binding of calcium to protein or lipids<sup>28</sup> as it was abolished when the vesicles were made freely permeable to calcium with ionophore A23187 ( $2 \mu\text{M}$ )<sup>29</sup>. In this system, the presence of azide excluded any possible participation of energy-dependent sequestration of calcium by contaminating mitochondria<sup>30,31</sup> and the persistence of calcium uptake activity in the absence of potassium suggests that uptake is not derived from the endoplasmic reticulum, which has been shown in adipocytes to be potassium dependent<sup>19</sup>.

The calcium-dependent regulatory protein, calmodulin, which stimulates ATP-dependent calcium uptake across red cell<sup>32</sup> and adipocyte<sup>11</sup> plasma membranes, had a similar effect in pancreatic islet cell plasma membrane vesicles (Fig. 3). In each of four experiments, calmodulin produced a significant ( $P < 0.05$  in a paired  $t$ -test) stimulation of ATP-dependent uptake (Fig. 3), ranging from 10 to 74% with a mean of  $36 \pm 15\%$ . Evaluation of a direct effect of calmodulin on the  $(\text{Ca}^{2+} + \text{Mg}^{2+})\text{ATPase}$  may require the presence of millimolar concentrations of magnesium (H.A.P. and J.M.McD., unpublished observations). Interpretation of the data is therefore complicated by the low affinity magnesium-stimulated ATPase and we are now investigating procedures to resolve this problem.

The demonstration of this high affinity  $(\text{Ca}^{2+} + \text{Mg}^{2+})\text{ATPase}$  associated with a calmodulin-stimulated active calcium transport system in pancreatic islet cell plasma membranes implies the presence of a mechanism capable of fine control of cytoplasmic free calcium concentration at the level of the plasma membrane. Calmodulin, which is present in pancreatic islets<sup>33</sup>, has been shown to activate adenylate cyclase<sup>34,35</sup> in this tissue, a mechanism which may serve to amplify the secretory response<sup>34</sup>. Activation of a calcium extrusion pump by calmodulin would provide a powerful means of negative feedback control of calcium and calcium plus calmodulin mediated effects on intermediary metabolism. Studies with intact islets using the calmodulin inhibitor, trifluoperazine, have suggested that calmodulin may play an important part in insulin secretion<sup>33</sup>. However, calmodulin regulates many diverse cellular metabolic events<sup>36</sup>, and thus its exact role in insulin secretion remains to be determined.

Whether or not the  $(\text{Ca}^{2+} + \text{Mg}^{2+})\text{ATPase}/\text{Ca}^{2+}$  pump complex is responsible for increased levels of cellular calcium in response to glucose stimulation is unknown, but this possibility can be easily tested using the model system described here. This cell-free system may provide a means of investigating the effects of other secretagogues and agents on calcium homeostasis at the level of the plasma membrane.

## Decamethonium and hexamethonium block $K^+$ channels of sarcoplasmic reticulum

Roberto Coronado\* & Christopher Miller†

Graduate Program in Biophysics and Graduate Department of Biochemistry, Brandeis University, Waltham, Massachusetts 02254

The sarcoplasmic reticulum membrane (SR) of skeletal muscle contains cation-selective channels which have been detected by isotope fluxes in fragmented SR vesicles<sup>1</sup>, fluorimetric dyes<sup>2</sup> and direct incorporation of SR vesicles to planar phospholipid bilayers<sup>3–5</sup>. SR channels incorporated in bilayers have a single open-state conductance of 140 pS in 0.1 M  $K^+$  (refs 4, 5). We have previously reported blockade of the SR channel by  $Cs^+$ , a low-affinity blocker with a zero-voltage dissociation constant of 40 mM (ref. 6). We showed that increasing  $Cs^+$  concentrations reduced the open-channel conductance, increased the mean open time and conferred voltage dependence on the open-state conductance<sup>6</sup>. Here we report on the blockade induced by the cholinergic drugs decamethonium and hexamethonium<sup>7</sup> on the SR channel. Although blockade by hexamethonium is similar to that of  $Cs^+$ , decamethonium blocks with a much higher affinity and induces flickering events which are probably due to the interaction of single drug molecules with the open state.

Figure 1 shows oscilloscope traces of single channel openings at  $-40$  mV for different concentrations of blocker. Addition of 10  $\mu$ M decamethonium induces flickering noise that is observed only when the channels are open. Higher concentrations increase the flickering rate, until at very high concentrations the flickering becomes faster than the amplifier time response; this results in an apparent reduction in the open-state conductance. At 300  $\mu$ M decamethonium this time-averaged conductance is about 10% of the control value. Figure 1 also shows that channels blocked with hexamethonium do not flicker, but rather undergo a smooth reduction in open-state conductance as drug concentration is increased. The amount of blocker necessary to reduce the open-state conductance to 50% of its original value is

**Fig. 1** Lipid bilayers were formed on polystyrene cups with 0.5-mm diameter holes using a 30 mM solution of Soy PE in decane. The aqueous phase was composed of symmetrical solutions of 50 mM  $K_2SO_4$  buffered with 1 mM HEPES-Tris/10  $\mu$ M EDTA, pH 7.2. Electrical measurements were made in voltage-clamp conditions using a Burr-Brown 3528CM amplifier. Output current was filtered using a low-pass active filter (Khron-Hite 3202) set at 20 Hz in all experiments except in the fast traces of Fig. 2c, where the cutoff was at 200 Hz. Current traces were taken from a storage oscilloscope and simultaneously recorded on chart paper. The *trans* chamber (side opposite to where SR vesicles are added) is defined as zero voltage. Incorporation of single SR vesicles was accomplished as described elsewhere<sup>4,5</sup>. Hexamethonium,  $(CH_3)_3N^+-(CH_2)_6-N^+(CH_3)_3$  and decamethonium,  $(CH_3)_3N^+-(CH_2)_{10}-N^+(CH_3)_3$  (bromide salts, Sigma) were added as glucuronate salts to the *trans* chamber in 50 mM  $K_2SO_4$  buffer. *a*, Traces of individual opening events at  $-40$  mV from the same membrane and at the concentrations of *trans* decamethonium (Deca) indicated. *b*, Channel openings from the same membrane at  $-40$  mV and concentrations of hexamethonium (Hexa) indicated. Experiments were done at room temperature, 21–22 °C.

120  $\mu$ M for decamethonium and 3.5 mM for hexamethonium at  $-40$  mV. Three important features of the block induced by decamethonium are shown in Fig. 2. Figure 2a shows that the flickering is voltage dependent. Flickering is observed only at voltages that drive the drug inside the channel (negative voltages). Figure 2b shows that flickering does not interfere with the gating process (that is, the voltage dependence of the open state<sup>4,5</sup>). A positive voltage was applied to open the channels and then returned to  $-50$  mV to observe the closing events. Repetitive flickering is observed but channels are still able to close at voltages that make the open state less probable<sup>4,5</sup>. The higher rate of flickering observed in Fig. 2 when five channels are open and its decrease as channels close strongly suggest that the drug blocks each channel independently. In Fig. 2c individual flickering events are displayed on a faster time scale. Traces were taken while a single channel was open. In the conditions specified the mean open time for this experiment was 3.5 s and the mean closed time 18–20 s. Addition of 20  $\mu$ M decamethonium segments the open state into much shorter dwell times ( $\sim 200$  ms). The individual flickering events, when they could be resolved, were square pulses that dropped the conductance from its open state value to zero and lasted less than 200 ms (see Fig. 2 legend).

We have recently concluded that conduction of cations through the SR channel occurs by movement of the ions across

**Fig. 2** Channels at low temperature in the presence of 20  $\mu$ M decamethonium added *trans*. Temperature was maintained at 7 °C using an ice-water bath. *a*, Recordings from the same membrane at -50 and +50 mV. *b*, Closing events at -50 mV after channels were open by holding the voltage at +50 mV (refs 4, 5). *c*, Recordings while a single channel opens at -50 mV and undergoes repetitive flickering. The mean open time of the open state in this experiment was 3.5 s and the mean closed time was 19.3 s (measurements done before addition of drug). The conductance drop during individual blocking events, measured in the cases where they could be resolved, was  $72 \pm 2$  pS ( $n = 10$ ) whereas the open-state conductance, measured in between flickering, was  $71 \pm 0.5$  pS ( $n = 20$ ). Blocking events were defined as apparent 'closed' states lasting less than 100 ms. These short-lived "closed" dwell times were observed only when the drug was present.

**Fig. 3** Voltage-dependent single-channel conductance in symmetrical solutions of 50 mM  $K_2SO_4$  buffer plus 100  $\mu$ M decamethonium or 1 mM hexamethonium. To obtain reliable measurements of the time-average conductance of channels with decamethonium, flickering was filtered using the amplifier with a time resolution of 0.5 s. This allowed measurement of a smooth d.c. value for the average open-state conductance. A total of 169 determinations from 4 membranes for decamethonium and 135 determinations from 7 membranes for hexamethonium were used to fit the curves. Bars indicate s.e.m.; the solid lines correspond to the single-site blocking equilibria<sup>6,9</sup> described by equation (1) below and the parameters given in the text

$$\langle \gamma \rangle / \gamma_0 = [1 + (B/K_0) \exp(z\delta FV/RT)]^{-1} \quad (1)$$

Where  $\langle \gamma \rangle$  is the time-averaged conductance in the presence of constant blocker at concentration  $B$ ;  $\gamma_0 = 140$  pS is the unblocked open-state conductance;  $K_0$  is the dissociation constant of the blocking reaction at zero volts;  $z$  is the valence of the blocking ion;  $\delta$  is the fraction of the total electric potential drop across the membrane found at the blocking site;  $V$  is the applied voltage;  $R$ ,  $T$ ,  $F$  have their usual meanings. Parameters for the fitted curves were obtained from a linearized form of equation (1) as described previously<sup>6</sup>. These parameters are  $K_0 = 11 \pm 0.5$  mM,  $z\delta = -0.66 \pm 0.02$  for hexamethonium and  $K_0 = 1.2 \pm 0.2$  mM,  $z\delta = -1.22 \pm 0.08$  for decamethonium.

three kinetic barriers and that the channel can accommodate at most one ion at a time (two sites, three barriers, one-ion Eyring model)<sup>12</sup>. The one-ion condition implies that the channel can accommodate a blocker ion or a conducting ion but not both simultaneously. Thus, we propose that the short-lived non-conducting dwell times observed in the presence of decamethonium correspond to blocking events generated by single drug molecules as they bind to the conducting channel. Flickering would then be the consequence of the reversible equilibrium of the blocking reaction. A one-site one-blocker model predicts that the time-averaged open-state conductance should decrease in the presence of the drug and that this average should be voltage dependent<sup>6,9-11</sup>.

An expression that combines the single-site binding with the voltage dependence of the dissociation constant is given by equation (1) shown in Fig. 3 legend. In Fig. 3 we measured the time-averaged conductance  $\langle \gamma \rangle$  as a function of voltage at constant and symmetrical concentration of blocker. Starting from the unblocked open-state conductance of 140 pS at positive voltages, the conductance falls steeply at negative voltages for both hexamethonium and decamethonium. Thus, these drugs block only from the *trans* side of the membrane. The solid lines correspond to equation (1) with  $K_0 = 11$  mM,  $z\delta = -0.66$  for hexamethonium and  $K_0 = 1.2$  mM,  $z\delta = -1.22$  for decamethonium (see Fig. 3 legend for explanation of symbols). The fit is consistent with the one-site blocking model within the voltage range measured.

The qualitative difference between the two blockers (flickering compared with 'quiet' channels) would be attributable to differences in the lifetime of the blocked state. If a blocker molecule forms blocked states that are short lived with respect to

the time response of the amplifier (5 ms), we would observe only an average apparent open-state conductance equal to the time-average of true open and true blocked conductances<sup>11</sup>. This seems to be the case for hexamethonium and caesium<sup>6</sup> in this channel. Molecules forming long-lived blocked states would generate flickering of the open-state conductance. This seems to be the case for lidocaine derivatives in the acetylcholine-receptor channel<sup>10</sup>, for tetraalkylammonium ions in the amphotericin channel<sup>8</sup>, and for decamethonium, as described here.

**Fig. 4** One or two blocking site models for methonium derivatives. In the same spirit of the two-site conduction model proposed for the SR channel recently<sup>12</sup>, we propose that both molecules can block at the  $\text{Cs}^+$  site but in different conformations to account for  $z\delta$  values measured (upper part). The alternative, of block at different sites, implies that hexamethonium would also act in a bent conformation. We envision that for methonium molecules at least one of the energy barriers (the *cis*-facing barrier) must be higher than the rest because they block only from the *trans* side. This is shown at the energy profile at the bottom. The  $\text{Cs}^+$ -blocking site was determined previously<sup>6</sup> and corresponds to  $\delta = 0.37 \pm 0.01$  measured from the *cis* side;  $\delta$ , when measured from the *trans* side is equal to  $1 - \delta$  measured from the *cis* side.

We suggest two possible explanations for the different voltage dependences found for the two methonium blockers. As shown in Fig. 4, both molecules could possibly bind to the same site in the channel if hexamethonium blocks in a linear conformation with one charge inside the field and decamethonium in a bent conformation with both charges inside the field. In this case, the long-lived blocked states could be due to stabilization of the two charges of the molecules at the binding site. Alternatively, if both blockers act in bent conformations, the blocking site would be more external for hexamethonium than for decamethonium.

It is necessary to propose the unusual bent-over conformation for decamethonium (Fig. 4), with the two positively charged quaternary ammonium groups located in close proximity, both inside a channel structure, because of the following observations: (1) the channel seems to accommodate only one ion at a time<sup>12</sup>; (2) decamethonium blocks with an 'effective valence' of 1.2, indicating that more than one charge enters the field; (3) at least 18 different monovalent organic cations (decyltrimethylammonium among them) block the channel from the *trans* side with  $z\delta = -0.62 \pm 0.03$  (R.C., unpublished results). Fortunately, decamethonium is a simple molecule, and it will be possible to synthesize several analogues with locked-in conformations which should reveal the molecular requirements for block with high affinity, long-lived blocked states and strong voltage dependence.

We thank Dr Eve Marder for providing us with the methonium blockers, and Mr Jeff Stern for comments on the

manuscript. This work was supported by NIH grants R01-AM-19826-03, K04-AM-00354-02 and by a Dretzin fellowship of Brandeis University.

## Defective synthesis of HbE is due to reduced levels of $\beta^E$ mRNA

Joanne Traeger, W. G. Wood\*, J. B. Clegg & D. J. Weatherall

**Haemoglobin E ( $\alpha_2\beta_2^{26\text{Glu} \rightarrow \text{Lys}}$ )** is one of the commonest haemoglobin variants. There are an estimated 30 million carriers of the  $\beta^E$  gene in South-East Asia, where they comprise more than 50% of the population in some areas<sup>1,2</sup>; however, the reasons for this high frequency have never been adequately explained. Homozygotes for HbE may be mildly anaemic, but they do not have any clinical disability<sup>3,4</sup>. However, individuals heterozygous for both  $\beta^E$  and  $\beta$  thalassaemia (HbE/ $\beta$  thalassaemia) have a severe clinical disorder which in some cases may approach that seen in homozygous  $\beta$  thalassaemia<sup>3,5,6</sup> and which is by far the commonest form of symptomatic thalassaemia in the Indian subcontinent and South-East Asia. Haemoglobin E is the only common structural variant which interacts with  $\beta$  thalassaemia to produce such a severe disorder and the underlying mechanism of the interaction is not known. We have studied several homozygotes and heterozygotes for HbE and show here that the  $\beta^E$  chain is inefficiently synthesized and produces the phenotype of a mild form of  $\beta$  thalassaemia; hence, when inherited together with  $\beta$  thalassaemia it causes a marked  $\beta$ -chain deficit. Furthermore, the mechanism for the defective production of  $\beta^E$  chains seems to be a reduction of  $\beta^E$  mRNA, a most unexpected finding in a disorder caused by a single amino acid substitution and presumably by a single nucleotide change in the DNA of the  $\beta$  globin gene.

Five HbE homozygotes and nine heterozygotes were studied, all of South-East Asian origin. The presence of HbE was confirmed by peptide analysis in two cases and by a positive DCIP precipitation test<sup>7</sup> in the remainder. The  $\alpha$  gene status of all the cases was examined by restriction endonuclease mapping<sup>8</sup> and, with the exception of a single  $\alpha$  gene deletion in one of the HbE heterozygotes, normal  $\alpha$  gene maps were obtained.

All the homozygotes showed a reduced haemoglobin level and microcytic, poorly haemoglobinized red cells (Fig. 1). The heterozygotes also had a reduced amount of haemoglobin per cell, as reported previously<sup>9</sup>, and the proportion of HbE was only 25-30% (Fig. 1), significantly less than the 35-45% normally observed in heterozygotes for stable  $\beta$  chain

\* To whom correspondence should be addressed.

**Fig. 1** Haemoglobin level (a), mean cell haemoglobin (b) and % HbE (c) in homozygous (●) and heterozygous (○) carriers of the  $\beta^E$  gene. variants<sup>10</sup>. Separation of peripheral blood erythrocytes according to age, by high-speed centrifugation, showed no change in the proportion of HbE between old and young cells, demonstrating that there is no preferential loss of HbE as the cells age.

The measurement of globin chain synthesis in peripheral blood reticulocytes of five HbE homozygotes showed a marked deficit of  $\beta^E$  chain synthesis (Fig. 2a), with  $\alpha/\beta$  chain synthesis ratios similar to, or greater than, those normally observed in  $\beta$  thalassaemia heterozygotes. The synthesis of excess  $\alpha$  chains in these cells was confirmed by gel filtration of the  $^3\text{H}$ -leucine-labelled reticulocyte lysates<sup>11</sup>, where a pool of radioactive free  $\alpha$  chains could be easily demonstrated. Furthermore, fine precipitates, typical of the free  $\alpha$  chain precipitates found in  $\beta$  thalassaemia, were observed in the bone marrow normoblasts of two of these patients by electron microscopy (S. Wickramasinghe, personal communication).

Among the HbE heterozygotes, the  $\alpha/\beta^A + \beta^E$  ratios ranged from 1.03 to 2.19 (Fig. 2a), which, with the exception of the individual who also had  $\alpha$  thalassaemia, were always greater than those for the normal control incubation run in parallel. The mean  $\beta^A/\beta^E$  specific activity (c.p.m. per mg) ratio obtained after

**Fig. 2** a, Globin chain synthesis ratios in peripheral blood reticulocytes in normal (AA), heterozygous HbE (AE) and homozygous HbE (EE) individuals measured after 60 min incubation with  $^3\text{H}$ -leucine<sup>11</sup>. b, Ratios of  $\alpha/\beta$  globin RNA in the same individuals using the method described in ref. 14. The open symbols are the results from the individual shown by gene mapping to have one (out of four)  $\alpha$  gene deleted.

60 min incubation was  $1.24 \pm 0.20$ ; this provides further evidence that HbE is not an unstable haemoglobin, because if that were the case, such ratios would be less than 1.0.

The time course of globin chain synthesis was studied in three homozygotes and three heterozygotes (Fig. 3). Even at the earliest time point (2 min) there was no evidence that the specific activity of the  $\beta^E$  chains exceeded those of the  $\alpha$  and  $\beta^A$  chains, and in the heterozygotes the  $\beta^A/\beta^E$  chain synthesis ratios remained constant throughout the incubation period. This argues against rapid destruction of the newly synthesized  $\beta^E$  chains.

Globin chain synthesis was also measured in bone marrow aspirates from three homozygotes and two heterozygotes and in each case the  $\alpha/\text{non-}\alpha$  chain synthesis ratio was more balanced than in the corresponding peripheral blood sample (Fig. 4). This must in part reflect the proteolytic destruction of some of the excess  $\alpha$  chains, as has been shown to occur in  $\beta$  thalassaemia heterozygotes<sup>12,13</sup>. In the marrow of one of the heterozygotes the  $\beta^A/\beta^E$  synthesis ratio remained constant throughout a 60 min incubation, but in both heterozygotes this ratio was lower in the bone marrow (1.23, 0.91) than in the reticulocytes (1.51, 1.15) after a 60-min incubation.

**Fig. 3** a, The incorporation of  $^3\text{H}$ -leucine into the globin chains of a HbE heterozygote during a 60-min incubation of peripheral blood reticulocytes. b, A similar experiment with blood from a HbE homozygote.

These experiments produce clear evidence for the defective synthesis of  $\beta^E$  chains. To determine whether this occurs at, or before, the translational level, the amounts of  $\alpha$  or  $\beta$  globin mRNA in the reticulocytes of these individuals were measured. We have reported previously<sup>14</sup> that in carefully standardized conditions the  $\alpha/\beta$  globin mRNA ratios fall into non-overlapping groups of normal individuals and those with various forms of  $\alpha$  and  $\beta$  thalassaemia. The values obtained do not represent absolute mRNA values, but the results are valid for comparative purposes<sup>14</sup>. In the present study the  $\alpha/\beta$  mRNA ratios in five HbE homozygotes (Fig. 2b) ranged from 3.29 to 5.81. This is two- to threefold higher than the range of 1.62–2.22 (mean 1.98) found in eight normal individuals studied at the same time, and similar to the values of 3.7 and 3.9 obtained in two  $\beta$  thalassaemia heterozygotes examined in this laboratory. Clearly, the deficit of  $\beta^E$  chain synthesis is reflected by a similar deficit of  $\beta^E$  mRNA production. Furthermore, in seven HbE heterozygotes the  $\alpha/\beta^A + \beta^E$  mRNA ratios were significantly higher than in the normal controls (Fig. 2b).

These experiments demonstrate, therefore, that the low level of HbE is not primarily due to instability of the  $\beta^E$  chain<sup>15</sup>, or to incomplete association into tetramers<sup>16</sup>, as previously suggested, but results from deficient synthesis of  $\beta^E$  chains, as suggested by previous studies on isolated cases<sup>4,16,17</sup>. The reduced synthesis of HbE (to approximately half normal levels) means that the  $\beta^E$  gene acts like a mild form of  $\beta$  thalassaemia and explains why, in the homozygous state, it produces a phenotype

similar to  $\beta$  thalassaemia minor, and why on interaction with a  $\beta$  thalassaemia gene, it produces a severe clinical disorder. The demonstration that deficient synthesis of the  $\beta^E$  chain results from lowered amounts of  $\beta^E$  mRNA is completely unexpected for a structural globin chain variant which results from a single amino acid substitution and hence presumably from a single nucleotide change. It is difficult to see how this single base change could alter globin gene transcription, but it is possible that its position at codon 26, close to the boundary of coding

Fig. 4 Comparison of the  $\alpha/\beta$  globin chain synthesis ratios in peripheral blood reticulocytes and bone marrow in three HbE homozygotes (●) and two HbE heterozygotes (○).

and intervening sequences after codon 30, might interfere with nuclear RNA processing. It is also possible that this particular nucleotide is involved in the secondary structure of the mRNA and that its substitution results in mRNA instability. The finding that the specific activity of  $\beta^E$  chains is lower than that of  $\beta^A$  chains in the reticulocyte incubations and the increase in the  $\beta^A/\beta^E$  globin synthesis ratios from bone marrow to reticulocytes would be consistent with this mechanism but this is very indirect evidence and could only be confirmed by measurements of bone marrow cytoplasmic mRNA ratios.

The remaining possibility is that the base substitution is not the cause of the decreased  $\beta^E$  chain synthesis but that there is a mild  $\beta$  thalassaemia mutation in *cis* to the  $\beta^E$  mutation. This could have arisen by sequential mutations in the same  $\beta$  globin gene, in either order, or by recombination between genes carrying the  $\beta^E$  and  $\beta$  thalassaemia lesions. If this were the case, the high frequency of the  $\beta^E$  gene in South-East Asia may be the result of selection for the  $\beta$  thalassaemia phenotype and the presence of the structural variant may be incidental.

**Note added in proof:** Reduced amounts of  $\beta^E$  mRNA have also been observed in patients with HbE/ $\beta$  thalassaemia, as reported in abstract form by Berman *et al.*<sup>18</sup>.

## Amino acid sequence homology between cholera toxin and *Escherichia coli* heat-labile toxin

Walter S. Dallas\* & Stanley Falkow

Department of Microbiology and Immunology, University of Washington, Seattle, Washington 98195

Cholera toxin (CT) and the *Escherichia coli* heat-labile toxin (LT) are functionally, structurally and immunologically similar enterotoxins. Both toxins cause the elevation of cyclic AMP levels in gut epithelial cells<sup>1,2</sup> by catalysing the NAD-dependent ADP ribosylation of membrane proteins<sup>3–6</sup>. Each toxin is composed of two dissimilar subunits<sup>7,8</sup>. The A subunit has an enzymatic activity and is the adenylate cyclase-activating component of the enterotoxin<sup>4–11</sup>. The B subunit recognizes membrane components and binds the holotoxin to the target cell juxtaposing the A subunit with its substrates<sup>9,12</sup>. Binding studies and competition experiments indicate that the membrane receptors for cholera toxin B subunit (CT-B) and LT-B are similar but not identical<sup>13</sup> (these studies were performed before LT was purified to homogeneity). The monosialoganglioside GMI has been shown to be the receptor for the cholera toxin<sup>14</sup>, and it probably composes part of the receptor for LT. Gyles and Barnum<sup>15</sup> first reported that LT and cholera toxin were immunologically related, and it has subsequently been shown that they share common antigenic determinants in both A and B subunits<sup>16</sup>. The primary structure of CT-B has been determined<sup>17,18</sup>. We report here a comparison between the amino acid sequences of LT-B and CT-B. The nucleotide sequence of the LT-B cistron (*eltB*) was determined using a recombinant plasmid encoding LT<sup>9</sup>. Translation of this sequence revealed that LT-B and CT-B show significant amino acid sequence homology. In addition, several features of the *eltB* cistron were revealed by the sequence analysis.

Previously, we described the cloning of the LT genetic determinant<sup>19</sup>. Analysis of *in vitro* generated deletions in the LT gene showed that the gene was composed of two cistrons and established an approximate locus for both *eltA* (encoding LT-A) and *eltB* (encoding LT-B)<sup>9</sup>. The LT phenotypes encoded by various deletion plasmids indicated that *eltB* was located on a DNA fragment bounded by *Hind*III sites (Fig. 1). If *eltA* and *eltB* were adjacent cistrons, then the data further suggested that the N-terminus of LT-B would be coded by the smaller DNA fragment between the *Hind*III site and the *Eco*R1 site. Figure 2 shows the nucleotide sequence around the *Eco*R1 site. In most instances the nucleotide sequence of both strands was ascertained. The largest protein that could be encoded in this region was found to be 124 amino acids in length. The initiation codon for this protein was located 10 base pairs from the *Eco*R1 site, but not in the small DNA fragment as initially speculated.

The nucleotide sequence encoding this protein was translated into an amino acid sequence which was compared with the sequence of CT-B (Fig. 3). The N-terminus of mature CT-B is threonine and the C-terminus is asparagine. The putative LT-B amino acid sequence also had asparagine as the C-terminal amino acid. If one compares the next 102 amino acid residues starting from the C-terminus, 80 of the LT-B residues are identical to those of CT-B. This result represents 79% homology. Of the 22 amino acid residues that differ, a single base change in the *eltB* codon could account for 20 of the changes. The other two nonhomologous amino acids would require a minimum of two base changes in the *eltB* codon to result in the homologous amino acid as found in CT-B. There are no regions in which the nonhomologous amino acids are concentrated, but rather they seem to be scattered throughout the primary sequence, except for a run of 23 residues (47–69) that are identical between the two proteins. A mature LT-B

\* Present address: Cetus Corporation, 600 Bancroft Way, Berkeley, California 94710.

**Fig. 1** Schematic diagram of the LT DNA region. Bars indicate plasmid DNA that was deleted<sup>9</sup>. The effect of each deletion on LT-A and LT-B expression is shown. Restriction enzyme recognition sequences used for DNA sequencing are also shown.

would have three more acidic amino acid residues than CT-B, whereas CT-B would have two more basic residues than does LT-B. CT-B has a compositional molecular weight of 11,590, whereas that of mature LT-B is 11,780, the difference corroborating our earlier reports that LT-B was slightly larger than CT-B (see note added in proof)<sup>8,9</sup>.

The 21 additional amino acid residues encoded at the N-terminus of *eltB* are undoubtedly a leader sequence that directs the nascent protein through (into) the cell membrane(s) and is eventually cleaved from the molecule. This is suggested by: (1) A few prokaryotic leader sequences have been characterized and these sequences range from 20 to 23 residues in length<sup>20</sup>; the LT-B leader sequence would be 21 amino acids in length. (2) Like prelipoprotein, the LT-B leader sequence would be cleaved after a glycine residue<sup>21</sup>. (3) The leader sequence of LT-B resembles the leader sequence of prelipoprotein in that both polypeptides have several charged amino acid residues at the N-terminus followed by a region, ~60%, composed of hydrophobic amino acids. (4) There is evidence that LT is either a periplasmic protein<sup>22</sup> or an outer membrane-associated protein<sup>11</sup> and, therefore, it would be expected to possess a leader sequence.

One hundred and eighty nucleotides proximal to *eltB* have also been determined. None of these sequences has a Pribnow box-like structure which is characteristic of an RNA polymerase binding site. This result supports our earlier data which suggested that *eltA* and *eltB* are transcribed as a single polycistronic mRNA and that *eltA* was located next to the promoter<sup>9</sup>. There is a Shine-Dalgarno sequence<sup>23</sup> three nucleotides from the initiation codon of *eltB*. Five nucleotides in this region are complementary with five of the first 12 nucleotides at the 3' end of the 16S ribosomal RNA. The nucleotide adjacent to the initiation codon *eltB* is an A which has been reported to enhance ribosome

binding<sup>24</sup>. The presence of a ribosome binding site adjacent to *eltB* may explain the observation that LT-B is present in at least 5 M excess compared with LT-A, even though *eltA* is closer to the promoter<sup>9</sup>. This could be accounted for if the *eltB* ribosome binding site is more efficient than the *eltA* ribosome binding site and/or if the secondary structure of the mRNA enhances translation of *eltB* compared to *eltA*. Interestingly, no sequences characteristic of mRNA termination signals have been found in the DNA sequences distal to *eltB*. Preliminary sequencing information does suggest, however, that an additional protein may be encoded by the LT operon, but additional sequencing will be necessary to confirm or reject this conjecture.

Our sequencing information confirms the similarities between LT and CT. Knowledge of the nucleotide sequence of *eltB* should enable substitution of single amino acids by site-specific mutagenesis of a nucleotide in a codon and observation of the effect on protein function. The structural similarities shared by the adsorption proteins makes it tempting to speculate that immunity to LT-B might result in immunity to CT and neutralization of the toxin. In this regard, LT-B-producing *E. coli* might be potential live, oral vaccine candidates, both for LT-mediated diarrhoeal disease (in man and animals) and cholera.

We have successfully cloned *eltB* in such a way that it is being transcribed through the *lac* promoter and a protein is being made from this transcript that is structurally, functionally, and immunologically indiscernible from LT-B (manuscript in preparation). Using a strain harbouring this gene, we are pursuing the idea of an LT-B vaccine.

We thank Donna Montgomery and Jeff Bennetzen for technical assistance. This work was supported by Public Health Service grant AI-10885-09 from the National Institute of Allergy and Infectious Diseases. W.S.D. was supported by the Biological Infections grant T32A1079-02 from the NIH.

**Note added in proof:** Clements *et al.*<sup>25</sup> have reported the first 20 amino acids of LT-B isolated from *E. coli* K-12 carrying one of our LT plasmids. These amino acids are identical with the first 20 amino acids of our predicted mature LT-B amino acid sequence.

**Fig. 2** Nucleotide sequence of *eltB*. The nucleotide sequence was determined using the chemical method of Maxam and Gilbert<sup>26</sup>. DNA strands were radiolabelled by a kinase reaction or by end repair using DNA polymerase I Klenow fragment. The five underlined nucleotides are complementary with five of the first 12 nucleotides of the 16S ribosomal RNA. The amino acid labelled 1 is the proposed N-terminal amino acid residue of mature LT-B. Several restriction enzyme recognition sites are shown.

## Freezing induced change in ligand orientation in oxycobalt-myoglobin

Hiroshi Hori, Mássao Ikeda-Saito & Takashi Yonetani\*

Department of Biochemistry and Biophysics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania 19104 and INSERM Laboratory Unit 128, 34033 Montpellier, France

Single crystals of oxycobalt-myoglobin were examined by electron paramagnetic resonance (EPR) spectroscopy at ambient and cryogenic temperatures. The principal values and eigenvectors of the  $g$ -tensor and the hyperfine coupling tensor were determined. The Co—O—O bond angle was estimated to be  $125^\circ$  at ambient temperature. The single crystal EPR data of oxycobalt myoglobin at 77 K showed two sets of the principal values for  $g$  and hyperfine coupling tensors and eigenvectors, indicating that the bound oxygen molecule takes two distinct orientations. The result has demonstrated for the first time that the well defined change in the molecular orientation is induced upon freezing the biological macromolecule.

Oxycobalt-myoglobin (oxyCoMb) was prepared by recombination of globin from sperm whale myoglobin and cobaltous protoporphyrin IX, followed by CM-cellulose column chromatography according to the method of Yonetani *et al.*<sup>1</sup>. OxyCoMb was crystallized from ammonium sulphate-phosphate at pH 6.1 (refs 2, 3) in a space group  $P_2$ , with unit cell dimensions  $a = 64.51 \text{ \AA}$ ,  $b = 31.03 \text{ \AA}$ ,  $c = 34.82 \text{ \AA}$ ,  $\beta = 105.84^\circ$ , and a  $Z$  value of 2 (ref. 3). EPR measurements were performed with a Varian E-109 X-band spectrometer with 100 kHz field modulation, interfaced with a PDP 11/40 digital computer system for data acquisition and analysis. OxyCoMb crystals were mounted with a small amount of grease on a home-built two-circle Teflon goniometer<sup>4</sup> and held in a Varian immersion Dewar flask for 77 K measurements or in a Varian variable temperature Dewar for higher temperature measurements. The crystal on the goniometer was manually rotated every  $5^\circ$  and/or  $10^\circ$  around its crystallographic axes with a reproducibility of  $\pm 5^\circ$ . The EPR data of the resonance positions versus the angle of rotation were computer-fitted to Schonland's equation<sup>5</sup> to determine the angular dependence of  $g^2$  and  $A^2$  (the squares of the  $g$  values and hyperfine coupling-constants, respectively). The signs of the non-diagonal elements of  $g^2$  and  $A^2$  tensor were determined by measuring the angular dependence of  $g$  and  $A$  values around any direction in a single crystal with respect to its crystallographic axes. The principal values for these tensors and the eigenvectors with respect to the crystallographic axes, determined according to Schonland<sup>5</sup>, are summarized in Table 1.

At room temperature (300 K), oxyCoMb exhibits one unique set of  $g$  and  $A$  tensors, indicating that the paramagnetic centre or the metal-bound oxygen maintains a definitive molecular orientation relative to the crystallographic axes. The  $g$  and  $A$  tensors of oxyCoMb, however, do not share the same principal axis system with each other. The  $A$  tensors are principally determined by the 3d orbital of the cobalt ion. The EPR results

obtained at room temperature are compared with the X-ray structure of oxyCoMb, which was determined in an unfrozen state at  $-15^\circ\text{C}$  (ref. 3), and schematically illustrated in Fig. 1. The  $\xi$  axis associated with  $g_{\xi\xi} = 2.056$  does not lie along the O—O axis. Among the three principal axes of the  $g$ -tensor, the  $\zeta$  axis associated with  $g_{\zeta\zeta} = 2.003$  ( $\approx g_e$  or the  $g$  value of free electron) appears to be the nearest direction to the O—O axis. From the directional cosines of  $z$  and  $\zeta$  axes, the Co—O—O bond angle is calculated to be  $125^\circ$ , in good agreement with the results of the X-ray structural analysis<sup>3</sup>, in which the bound oxygen is shown to be oriented in the Pauling geometry with the Co—O—O bond angle of  $129^\circ$ . Note that the direction of the maximal  $A$  value, or  $A_{xx} = 18.12 \text{ G}$ , is parallel to the imidazole plane ( $C_\delta - C_\epsilon$ ) of the proximal histidine. Thus, the interaction between the  $p$  orbital of the imidazole ring of the proximal histidine and the 3d orbital of the cobalt ion, which has been previously proposed, cannot be verified from these results. The direction of  $A_{zz}$  is very close to the normal of the porphyrin plane within  $5^\circ$ , thus it is reasonable to assign  $A_{zz}$  to the direction of the Co—O<sub>1</sub> axis. However, the Co—O<sub>1</sub> bond is not strictly perpendicular to the porphyrin plane, but inclines approximately  $8^\circ$  from the normal of the porphyrin plane. On the other hand, the nearest axis to the direction of the O<sub>1</sub>—O<sub>2</sub> axis is the  $\zeta$  axis, which inclines about  $20^\circ$  from the direction of the O<sub>1</sub>—O<sub>2</sub> axis. These angles are larger than our experimental error of  $5^\circ$ .

The unpaired electron, which is responsible for EPR in oxygen adducts of cobaltous chelates including cobaltous porphyrins has been generally assigned to the  $\pi^*$  orbital of the bound oxygen and the bound oxygen molecule has been oriented in such a way that its orbital overlaps maximally with the 3d orbitals of the cobalt ion in previous EPR studies of these compounds. The interaction between the  $\pi^*$  orbital of O<sub>2</sub> and the 3d<sub>z<sup>2</sup></sub> orbital of Co<sup>2+</sup> (ref. 6) and the molecular orbital involving the  $\pi^*$  orbital of O<sub>2</sub> and the 3d<sub>z<sup>2</sup></sub> orbital of Co<sup>2+</sup> (ref. 7) have been proposed. In these theoretical treatments, which assume the unpaired electron in the  $\pi^*$  orbital of O<sub>2</sub>, the direction of the maximal  $g$  value ( $g_{\xi\xi}$ ) should inevitably lie along the O—O axis<sup>7</sup>. Contrary to this assumption, our single-crystal EPR results at room temperature suggest that the direction of  $g_{\xi\xi}$  ( $\approx g_e$ ) does lie along the O—O axis. This suggests the possible contribution of the antibonding orbital of  $\sigma$  bond of O<sub>2</sub> to the metal-oxygen bond, although we could not exclude that of the  $\pi^*$  orbital. We believe that steric interaction of the distal residues such as E7 His, E11 Val, and CD1 Phe as well as the proximal histidine (F8 His) would contribute significantly to the stereochemistry of the Co—O<sub>2</sub> bond and should be

**Table 1** The principal  $A^{\text{Co}}$  and  $g$  values and the directions in a single crystal

| Complex               | Temperature (K) | Principal values         | †Angle to: |            |       |

\*Present address: Abteilung Biochemie, Biozentrum der Universität Basel, Klingelbergstrasse 70, CH-4056, Basel, Switzerland.

incorporated in the theoretical calculation of the Co—O<sub>2</sub> bonding.

The single-crystal EPR data of oxyCoMb at 77 K are much more complex: two sets of the principal values for  $g$  and  $A$  tensors and eigenvectors are found, indicating that the bound oxygen molecule takes two distinct orientations (species I and II), confirming the previous observation of Chien and Dickinson<sup>8</sup>. However, these workers report different principal values and eigenvectors of  $A$  and  $g$  tensors from our own. The origin of these differences is not clear. However, there are two solutions for selecting the signs of the non-diagonal elements of  $g^2$  or  $A^2$  tensors, only one of which is correct. Figure 2 illustrates the Co—O—O bonding structure and the projections of the directions of  $A_{xx}$ ,  $A_{yy}$ , and  $g_{zz}$  onto the porphyrin plane, together with those of proximal and distal residues, which are determined from our single-crystal EPR measurements at 77 K. If we assume that the direction of  $A_{zz}$  is fixed approximately to the normal of the porphyrin plane, the directions of the maximal  $A$  values for species I and II produce an angle of about 90° in the porphyrin plane. If the axis associated with its  $g$  values nearest to  $g_e$  is taken as the O—O axis, in accordance with the room temperature data, the Co—O—O bond angle becomes 93° ( $g_{zz} \wedge A_{zz}^I$ ) for species I and 163° ( $g_{zz} \wedge A_{zz}^{II}$ ) for species II, respectively. These two directions of the O—O axis nearly coincide with the direction of the imidazole plane ( $C_\delta$ — $C_\epsilon$ ) of the distal histidine. On the other hand, if the  $\xi$  axis (the direction of the maximal  $g$  value) is taken to be the O—O axis, the Co—O—O bond angle becomes 111° for species I and 108° for species II, and each  $\xi$  axis is oriented almost in the direction of its maximal  $A$ -value, respectively. However, it cannot be determined which axis should be the O—O axis in the 77 K EPR conditions. Whichever one is taken as the O—O axis, the direction of the O—O axis at 77 K is definitely different from that observed at room temperature.

In a previous single-crystal EPR study at 77 K (ref. 8), it was concluded that the bound oxygen molecule in oxyCoMb takes two types of orientation (species I and II) which are more or less in the Griffith parallel geometry. However, we find that the two orientations of oxygen in oxyCoMb at 77 K are best described

**Fig. 1** The bonding structure of Co—O<sub>2</sub> and the directions of  $g$  and  $A$  tensor (room temperature): Co—O—O bond angle and the directions of  $A_{zz}$  and  $g_{zz}$  are shown (upper). The projections of  $A_{xx}$ ,  $A_{yy}$ ,  $g_{zz}$ , and O—O axis onto the porphyrin plane are shown (lower), from the proximal-side view. The projections of the distal residues are shown by dotted lines.

**Fig. 2** The bonding structure of Co—O<sub>2</sub> (77 K); the directions of the maximal  $A$ -values for species I ( $A_{yy}^I$ ) and for species II ( $A_{xx}^{II}$ ) are shown (lower).  $\xi$ -axis is assumed to be fixed on the O—O axis. The two species (I and II) are oriented about 90° to each other in the crystal (upper).

by Pauling bent geometry, neither of which is identical to its Pauling orientation at room temperature (see Figs 1 and 2). EPR measurements at different temperatures indicated that the transition between one potential-well at room temperature and two potential-wells at 77 K for the oxygen binding in CoMb is a reversible process and takes place at/near the freezing point of crystals.

Adverse effects of solvent freezing on biological compounds are well recognized but only limited data are currently available. Examples are abrupt changes in the paramagnetic susceptibility in haemoglobin near freezing point<sup>9</sup> and the loss of the ordered intermolecular arrangement in crystals of cytochrome *c* peroxidase on freezing<sup>10</sup>. The present single-crystal EPR study shows for the first time that a well defined change in the molecular orientation is induced by freezing of a biological macromolecule. Since magnetic and spectroscopic measurements of biological macromolecules, particularly metalloproteins, are by necessity carried out in a wide range of ambient and cryogenic temperatures, it is important to recognize that the analyses of experimental data and theoretical interpretation of such data must take into account the possible adverse effects of freezing, as demonstrated here.

We thank Dr G. Petsko for the coordinates of the X-ray structure of oxyCoMb and Drs G. Petsko, P. Douzou, and T. Inubushi for stimulating discussions. This work was supported by research grants from the National Heart, Lung, and Blood Institute (HL 14508) and the NSF (PCM79-22841).

# CHRISTMAS BOOKS SUPPLEMENT

## From Dan to Beersheba, and beyond

P.J. Parr

THERE was a time, in the late nineteenth and early twentieth centuries, when a desire to illuminate, explain and even to vindicate the Bible provided the chief motive force behind much of the archaeological exploration of the Near East — of Mesopotamia and Egypt, and of Palestine itself. Archaeology has changed in recent years, however, both in its goals and its methods, and its practitioners in the Holy Land today are likely to be as concerned with such problems as the diet of Neolithic man or the mechanisms of Bronze Age trade as they are with the date of the Exodus, the design of Solomon's temple or the location of the tomb of Christ. In academic circles Biblical archaeology has certainly lost much of its former prestige; which is, on the whole, not a bad thing. Nevertheless, it remains probably the most popular branch of the subject amongst the educated lay public, for the simple reason that Palestine — as Moshe Pearlman admirably puts it in his book *Digging up the Bible* (Morrow/Weidenfeld & Nicolson, \$19.95/£8.95) — “is the only region of antiquity of which there is a written historical record that has been familiar to so many people in every generation for so long”. The writer of a book catering for this interest has a duty to be readable, accurate and reliable, and to add something new to the already vast literature available, and it is by these criteria that all of the three new books reviewed here should be judged.

Pearlman's volume is certainly the least satisfactory, despite the fact that it is well-written and produced, with many pertinent and attractive illustrations and a lively text. His re-telling of the “stories behind the great archaeological discoveries of the Holy Land” is substantially accurate, though they have all been told before. It is a pity that, as the account nears the present day, there is a definite over-emphasis on

Erosion features in the Sinai

Israeli research at the expense of that carried out by foreign scholars; for example, the important work of Kathleen Kenyon at Jerusalem just before the Six Day War receives scant mention, while the excavations of Roland de Vaux (one of France's most outstanding Biblical archaeologists) at Qumran, where the Dead Sea Scrolls were written, are not referred to at all, although the Scrolls themselves are given a dozen pages of text. The book's chief fault lies in the dubious nature of some of its archaeological statements, however. Thus (at random) the Hyksos are no longer seen as a “northern people” by most scholars (p.146); the date of the Exodus has not been proved just by the discovery of a few pieces of Mycenaean pottery at Hazor (pp.71–72) — it has, in fact, not yet been satisfactorily established that there really was an Exodus; the date of the Neolithic tower at Jericho has been known for over a decade to be at least a thousand years earlier than the date of 6850 BC quoted on p.141. Even a popular book has to be less misleading and simplistic than this.

Father Murphy O'Connor's *The Holy Land: An Archaeological Guide from Early Times* (Oxford University Press; hbk

£8.50, \$15; pbk £3.95, \$5.95) is much more reliable, though it too has its faults. Almost everything written on the dust jacket is true: it is “concise, readable and wittily erudite . . . its scope is wide . . . it gives clear directions [and has] numerous detailed plans”. It differs from — and adds to — most comparable books by giving a prominent place to many of the less well known and accessible sites and monuments, especially of the Byzantine and Crusader periods, with which the author — who is Professor of New Testament at the Ecole Biblique in Jerusalem — is clearly most familiar. It is, conversely, perhaps a little thin on some of the pre-Israelite remains (the important Canaanite temples of Area H at Hazor, for example), and the brief discussion in the opening pages of the early history of the country is really much too short to be useful to anyone, and includes some statements (for instance, the date of the Neolithic Revolution; the date and nature of Abraham's journey from Mesopotamia) which are as simplistic and inaccurate as some of Pearlman's. But this is the only flaw in an otherwise excellent guide, which should be in the luggage of every visitor to the Holy Land.

P. J. Parr is Senior Lecturer in the Archaeology of Western Asia at the Institute of Archaeology, University of London.

Simon McBride

The third volume, *Sinai* (Kümmerly and Frey, Berne, SF88), edited by Beno Rothenberg, is remarkable for achieving a very successful synthesis of attractive coffee-table format and serious academic text between the same two covers. Its hundred-odd colour photographs, by Helfried Weyer, are outstandingly beautiful, and the only danger is that they will distract the reader from the text. This would be a pity. It consists of a number of concise but scholarly chapters not only on the archaeology and history (ancient and modern) of the peninsula, but also on the environmental background (geology,

mineral resources, flora, fauna) essential for an appreciation of that history. The archaeological chapters are based mainly on the fieldwork of Rothenberg himself, and present some of the results for the first time in English. Rothenberg does not avoid technicalities and sometimes indulges in jargon; but the terms are usually explained, the arguments logically presented and the accompanying plans and diagrams attractively informative — all in the best traditions of popularization. These archaeological discoveries in Sinai are mostly related to periods long pre-dating the Israelites, and have little direct bearing on Biblical archaeology, in its narrow sense. But the book provides a vivid and reliable demonstration of the sorts of problems and categories of evidence now engaging the attention of archaeologists in Palestine, and as such is to be warmly recommended.

*Sinai* is available in the UK from The Museum Bookshop, 36 Great Russell St, London WC1 3PP, price £20, and in the US from J.J. Binns, 6919 Radnor Rd, Bethesda, Maryland.

reproduced are fuzzy and faint, and are plainly failures which a critical photographer normally consigns to the waste-paper basket. They do not captivate and entrance us, as the author surmises. For her they represent "a dream world of symbols and queer relationships . . . that naively ask questions pertaining to life and death, time and motion". The author slips quite easily from science to poetic flights, a nice feature but we have to come back to the ground. The poor reproduction of the photographs is due to a cardinal mistake in this American production in printing them on text instead of art paper. Neither in colour nor in contrast do the sepia reproductions approach the quality of the originals. Only those few examples printed in red, purple and primrose — colours imparted to the calotypes by use of different fixing salts — fulfil this expectation, and they are beautiful.

In any new edition I would recommend the correction of a few statements; I will mention just three. Talbot's discovery of the latent image was a vital element in his calotype process. Yet Daguerre had made the same discovery five years earlier in his. It is therefore wrong to use the term "photography" which covers both methods. Talbot's wife Constance was not the first woman photographer. Madame Giroux, wife of the manufacturer of the official Daguerre camera, in 1839–1840 supplied each outfit with a sample daguerreotype taken by herself. *The Pencil of Nature* was published in six parts over a period of two years, the last appearing in April 1846 (not 1845).

The history of photography has been enriched by two recent biographies of one of the inventors of the process. Both of them are valuable additions to the literature, but neither is objective enough to be considered definitive. Hero worship is a poor partner of truth.

*Helmut Gernsheim is a photohistorian and Distinguished Visiting Professor at the Universities of Texas and Arizona. In 1959 he was the first recipient of the Kulturpreis for photography.*

## Negative and positive of Fox Talbot

Helmut Gernsheim

*Fox Talbot and the Invention of Photography.* By Gail Buckland. Pp.216. (Scolar/David Godine: 1980.) £20, \$50.

WILLIAM Henry Fox Talbot FRS, inventor of the negative/positive method of photography on which modern photography is based, patentee of halftone photo-engraving, of electric flash photography and a number of other important contributions to the development of photography, was a brilliant scholar in several fields of science. Yet an unfortunate mania for pursuing patents, for commercial enterprises and for law suits earned him more animosity than cash the impoverished owner of the ancient abbey and village of Lacock needed to rebuild the family fortunes.

In his belief that every photographic process with the exception of the daguerreotype was only a variation of his own, Fox Talbot effectively prevented important improvements, freely published by others, from becoming common property in England, thus severely impeding the progress of photography. However, his claim to Frederick Scott Archer's collodion process on glass, which was about to oust his own method on paper, outraged English photographers, fellow scientists and editors of journals and they combined to defend photography from further interference; Talbot lost the case in December 1854. With the new-won freedom to compete with other countries, a golden age of invention and creativity set in giving Britain a leading position with France in the latter half of the nineteenth century. As neither Daguerre's nor Talbot's patents included Scotland the position there was quite different. The finest calotype portraits and some of the

best waxed-paper photographs in existence were produced in Edinburgh in the 1840s and early 1850s.

Probably out of a false respect for her hero, little of this strangulation of English photography in its early formative period (1841–1854) emerges in Mrs Buckland's book. Similarly, H. J. P. Arnold, in his biography of Talbot (Hutchinson, 1977) which preceded hers by three years, tried hard to belittle the strong contemporary evidence of Talbot's machinations. Anyone interested in a rather different view of Talbot can find it in my *History of Photography* (Oxford University Press, 2nd Edn 1969) and in R. Derek Wood's detailed study of Talbot's law suits (*Annals of Science* 1971 and 1975).

The 230 photographs partly integrated with Mrs Buckland's text, and partly added to it in album fashion, plus the many interesting excerpts from letters and journals, make her monograph particularly valuable. Yet many of the calotypes

"The Open Door", March 1843. The picture that made Talbot "certain that he could give form to his creative instincts . . .".

Science Museum, London

## More variations on a biological theme

Ashley Montagu

*The Panda's Thumb.* By Stephen Jay Gould. Pp.343. (W.W. Norton: 1980.) \$11.95. To be published in the UK in spring 1981, £6.95.

RECENTLY a young student of mine, having ably presented a seminar on Stephen Jay Gould's admirable book, *Ontogeny and Phylogeny* (Harvard University Press, 1977), asked me what Gould's specialty was. Only one answer was possible: versatility. Gould is a professor at Harvard and lectures on geology and palaeontology; he also teaches courses in biology and the history of science, and writes on physical and biological anthropology, growth and development, evolutionary theory, human nature, intelligence testing and sociobiology, to name but a few areas of his competence. In addition he is a highly regarded reviewer in scientific and literary journals and magazines. To cap it all, he writes a monthly column, "This View of Life", in the magazine *Natural History*.

It is from the column that this anthology, lightly edited, has been put together. Gould's earlier collection of essays from the same source, *Ever Since Darwin* (W.W. Norton), appeared in 1977. That volume immediately established him as perhaps the best of our natural history essayists. As a friend remarked the other day, "Whatever he writes is a gift".

In the prologue to the 31 pieces which make up this new volume, Gould expresses the hope that he has avoided that incubus of essay collections: diffuse incoherence. Neither author nor reader need have any qualms on that or any other score: the essays are consistently coherent and follow naturally, one upon the other, as if they were chapters on a single theme. There is a continuity which runs through this eminently readable book like a red thread, giving it a unity behind which an unusual mind is at work trying to figure out, among other things, how multicellular creatures regulate the timing involved in the complex orchestration of their embryonic growth, in the hope that developmental biology might one day unite molecular genetics with natural history to form a unified science of life. In one way or another these essays are mostly directed toward illuminating the routes to be taken to solve that problem.

The book plays variations upon this theme most delightfully, for in addition to being the best-informed of writers, Gould is also one of the most elegant. He is unfailingly interesting, for he has the rare gift of communicating the excitement he feels about whatever his fertile brain encounters. The reader comes away enriched and entertained at the same time. From the first essay, from which the book takes its title, in which the author discusses

the manner and the method of evolution, to the last, in which he shows, by way of the chambered nautilus, how the palaeontologist has come to the rescue of the geophysicist and mathematician in arriving at a sound estimate of the rotational slowing of our planet, Gould holds the general principle of evolution steadily in view.

In an essay on Darwin and Wallace, Gould shows how the latter, one of the most remarkable and underestimated of thinkers, ultimately became an intellectual victim of his own hyperselectionism, in arguing that the excessive complexity of the human brain could not have been produced by selection. In another essay, "Darwin's Middle Road", the author writes revealingly of the fibs that the great man told about his insights. Here it is good to see Gould recognizing what few ever do in discussing the historical background of the Wallace-Darwin theory, namely, the role played by sociopolitical ideas, a fact clarified by Patrick Geddes in the late

nineteenth century and by Charles Sanders Peirce almost as long ago.

In this essay Gould errs in saying that what was presented at the famous Linnean Society meeting of 1858 was "a joint paper". Though this is often stated, the truth is that what was presented, in the absence of both men, was an extract communicated in 1844 to Lyell and a letter to Asa Gray of 1857 (both by Darwin) and at the same time, but separately, Wallace's 1858 essay "On The Tendency of Variations to Depart from the Original Type". The communications were presented *together*. There was no joint paper as such.

But Gould rarely nods. On the few occasions on which he does he challenges one furiously to think. His book is a treasure. □

Ashley Montagu is a biological and cultural anthropologist. He is editor of the recently published *Sociobiology Examined* (Oxford University Press).

## Contrary natures

Richard Mabey

THE ideal countryside of the book-packager is all things to all possible buyers: visible, walkable, edible, amenable to identification and to technicolour display, wonderfully awesome without ever being fundamentally mysterious. When Felix Gluck Press put together *Nature Through the Seasons* and *Nature Day and Night* for Penguin/Viking (now issued as paperbacks at £1.95/\$4.95 and £2.50/\$7.95 respectively) they took this principle to its depressingly logical conclusion and interweaved quite separate contributions by a writer, an artist and a scientist — the days being long past, presumably, when one person could be expected to be all three. The series of cameos in each book begins with an imaginative scene setter ("A Rocky Coast by Day", for example), continues with a "science text" ("Tides and Internal Clocks"), and is rounded off by one of those breathless habitat collages which look as if they are depicting local assembly points for the Ark.

Max Hooper's science notes are, as you would expect, lively and entertaining; David Goddard's set-pieces — all sharp edges and precise little tessellations of colour — are meant, I suppose, to be some kind of half-way stage between the scientific and poetic visions, but end up looking as stiffly unnatural as paintings-by-numbers. Neither seem to grow in any convincing way out of Richard Adams's wonderfully evocative introductory essays. For anyone who finds his fiction a little

indigestible these are a revelation. He meanders through his favourite landscapes, sniffing, listening, exulting, reflecting, but without being intrusive in any way, and succeeds in capturing the exact flavour of *moments* in nature, from the small hint of spring in the first brimstone butterfly, to the flowing away of the whole year in a leafless winter wood.

The ingredients which have been sandwiched together in Hodder and Stoughton's series *The Natural History of Britain and Northern Europe* are a lightning guide to the ecology of each habitat and a European field guide. The latest volume by Brian Whitton, *Rivers, Lakes and Marshes* (£5.50), ends up being rather unsatisfying on both counts. It was surely a mistake to try and produce a digest of the aquatic flora and fauna of half a continent, couched in scientific language yet marketed for tourists. What would your botanically-inclined riverside picnicker make, I wonder, of a branched bur-reed whose description reads "Lvs erect, <15mm wide, keeled, triangular in section, ♂ and ♀ fls in separate, spherical heads; in branched inflo., ♂ above, ♀ below"? A bee-line for the sandwiches rather than the glossary, I would imagine.

At least *Nature Detective* by Hugh Falkus (Penguin, £2.95) takes the view that there is more to the study of nature than the naming of parts, and presents an entertaining guide to forensic field biology. The countryside is littered with physical clues

about animal encounters: tracks, scratchings, suspicious mounds, discarded skins, decapitated corpses, each one with its distinctive "MO" as they call it in Criminal Records. Again, it is a rather narrowly materialistic view of the natural world, but at least the tone of the writing — and of the captions in particular — encourages you to go sleuthing with a light heart. The photographs, mostly by Niko Tinbergen, are superb, and take this book beyond the purely anecdotal. One, of the heraldic print of a raven's wings in deep snow, suggests an ancient survival myth way outside admissible evidence.

One needs to be something of a nature detective to work out what on Earth is going on in the anonymous *The Twelve Months of the Year* (David and Charles; hbk £5.95, £16.95; pbk £3.95, \$11.50) so scrappy, inaccurate and disorganized are its contents. But clues to the conspiracy (and the motivation) are plain enough: a photograph of a red-backed shrike with young (in the February section!) mislabelled as a great grey shrike; common mouse-ear equated with chickweed — rather alarmingly, since a few pages later you are encouraged to eat it; those habitat collages again, with crows cohabiting with cranes, black woodpeckers in the beechwoods and hamsters in the corn. This is a world we have never encountered naturally in Britain, and you do not need to check in the picture credits to realize that this was originally a Dutch volume which has been hurriedly adapted, entirely unexplained, for a British audience. It is as cynical an exercise in book-making as I have ever seen, and I feel rather sorry for the British author who has translated or added to parts of the text (unacknowledged, even though he or she writes in the first person) as these fragments are really rather good.

Gordon Benningfield has provided (and signed) both text and pictures for *Benningfield's Countryside* (Allen Lane/Viking, £7.95/\$19.95). His paintings are as accomplished and idyllic as usual.

What is the surprise in this book is the quality of his prose, which has a mixture of unaffected strength and personal vision that is now sadly rare in English country literature. He writes uncompromisingly about the devastation wrought to his childhood countryside, about the forces that draw him to painting, and best of all about the business of putting a picture together. I must confess that I like his big soft, pastoral landscapes least of all his work, but his notes on why they were composed just so at least made me look at them with a new curiosity:

I have also put a glimpse of deer into my large painting of a typical piece of Ashridge [in Hertfordshire] at bluebell time, in May . . . The deer have just seen me and are about to move off; in a moment, they will have disappeared altogether. I wanted to convey the feeling that wildlife is not at all obvious in the countryside, that it is just a piece of luck that it has appeared at this moment.

Along with his prose, I think Benningfield's strengths lie in his detailed portraits, quite unidealized, of butterflies and gates and mucky field corners. It would be exciting, then, to see some of the outrage he expresses in his writing worked out in his painting.

Compartmentalization of the ways we look at and talk about the natural world is now dangerously endemic. Gordon

Benningfield is a man of sufficient popular appeal and broad-based skills to be able to make the kind of coherent personal statements that are normally anathema to contemporary publishers.

*Richard Mabey is a writer specializing in conservation and countryside matters. His most recent book is The Flowering of Britain, published by Hutchinson.*

## In the wake of the *Beagle*

Arthur Bourne

*The Yachtsman's Naturalist.* By Maldwin Drummond and Paul Rodhouse. Pp.270. (Angus & Robertson: 1980.) £8.95.

NOSING about the coastlines of western and north-western Europe covered by this book is one of the most rewarding occupations open to the yachtsman. These rewards are greatly increased if the navigator combines his art with an understanding of and a curiosity about the natural world around and beneath him. If his curiosity extends to exploring that world, then it requires only a small push to hook him into doing some real science.

The push can come in many guises, most often through the infectious enthusiasm of a friend or a book. There used to be an excellent book but it is now long out of print and most of us have had to rely on the enthusiastic friend. So there is a need for a guide designed especially for the amateur marine biologist and oceanographer and the present volume is intended to fill that need. The question is does it do so?

In Part one, which consists of three chapters, the authors describe the ecology of the coastal zone, from the land, down the shore to the water column itself. This part of the book is excellent and one could not wish for a better introduction to the subject. Part two, covering seamanship and equipment, has only two chapters and is more condensed. It is less satisfactory and gives the feeling that the authors were in a hurry and used scissors and paste in an attempt to finish quickly.

The chapter on seamanship and long-shoremanship begins with an interesting and informative description of the sort of seamanship required of the yachtsman if he is to navigate and lie safely close in to the shore — necessary if he is to observe the natural scene to best advantage. Such matters as the most effective way of anchoring, types of anchors and their weights, lengths of warp are dealt with in some detail, including the all-important — and often neglected — subject of drying out. Unfortunately little else! The equipment needed for the yachtsman/naturalist (now, by the way, called the sailor/naturalist), including the yacht

itself, comes in the final chapter. My own preference would have been to have placed choosing a yacht right at the start of Part two and I would have liked to have seen some more detail. The authors give only two pages to what is not only the most expensive piece of equipment but the most important. The rest of the equipment and its use is covered reasonably comprehensively, though the amount of detail varies and reflects, probably, the interests of the authors.

A feature of the book is the colour plates, illustrating animals and plants of the coast and sea, which are slotted into the book in six groups of two. The names of the organisms are provided on the backs of the plates and a numbered key aids rapid identification. The same key is used in the text where the organisms are mentioned. This arrangement works well. The plates themselves are adequate; one can recognize the organisms and perhaps that is all one requires. They do make the book colourful but I cannot agree with the authors that the plates make the book. They do not. What makes the book is the writing and the obvious enthusiasm of the writers. There are also large numbers of line drawings but these are poor except for those showing equipment and boats where the artist is particularly good at portraying yachts in the transparent shorescapes.

These are only small criticisms and perhaps we should go back to the question as to whether the book fills the need? Yes and no. As a personal preference I would like to have seen Part two as well developed as Part one, but, overall, the authors have provided a sound, useful and stimulating volume. I suppose one should ask of this sort of book whether it works, given its limitations, often dictated by constraints of size and costs. Would a yachtsman with this book be able to increase his knowledge of the natural scene about him? I believe the answer must be an unqualified yes. I hope it will find a place on the shelves of yachtsmen and naturalists alike. □

*Arthur Bourne has a special interest in coastal zone ecology and has been a member of many shipborne expeditions from the tropics to the higher latitudes.*

## Rare gifts of botanical illustration

Peter D. Moore

THE art of botanical illustration has presented a great challenge to many who have been fascinated by the structure and colour of flowers, and who have sought to represent these in two dimensions. Science is itself an attempt to describe with precision the world in which we live, and the graphic arts have proved a valuable consort to the physical sciences and mathematics in achieving this end. In no area of science is this more true than in botany, where much early, observational work was assisted by the skills of artistic illustration. The three books reviewed here are splendid examples of the contribution which art makes to the understanding, appreciation and enjoyment of plants and, indeed, the contribution made by the plant to art.

The life and work of Marianne North, set out in *A Vision of Eden* (Holt, Rinehart and Winston/Webb and Bower, \$22.50/£8.95), is a prime example of the mixing of art and science. It is the autobiography of an unmarried Victorian lady who, at the age of 40 and on the death of her father, took to a life of travel, and recorded in paintings the vegetation of the areas she visited. It is a story of amazing courage, for the hazards of travel in the 1870s were quite formidable, but she tackled both these and her art with devotion and fortitude. The result was a large collection of botanical illustrations from many areas of the world and an extensive selection of these is presented in this book.

Marianne North, 1886

An interesting aspect of Marianne North's work is the varied way in which she presented her botanical subjects. Some illustrations are entirely devoted to a single plant, in which close detail of structure is represented. Some take the form of still-life groups in delicate arrangements. Other plants are shown in natural settings, with birds and butterflies and other insects in

attendance. But, to my mind, her most artistically appealing works are those in which the plant becomes the foreground to a landscape. Her paintings from northern India, for example, together with her vivid descriptions of the dust, the heat and the inevitable sickness, rival the works of Forster and Masters in conveying the unique atmosphere of that part of the world. As a book of travel stories from a century ago, this book is particularly valuable, for it provides us with botanically detailed descriptions of many areas which, like the Himalayas, are now greatly changed under the impact of increasing human exploitation.

Among our modern painters of flowers, the name of Marjorie Blamey is outstanding. In her latest book, *Flowers of the Countryside*, produced in cooperation with Philip Blamey (Collins/Morrow, £8.95/\$25) she has assumed the role of author as well as illustrator. The text is something of a botanical scrapbook, parts autobiographical, parts historical and parts anecdotal. It is in no way a botanical textbook and it is unclear what purpose it is intended to serve. A large portion of the book consists of a survey of the major British plant families, of which selected species are illustrated and described; yet this cannot be regarded as a field guide. The paintings are both accurate and pleasing, and I am sure that many who buy this book will be motivated by an admiration of these pictures, which are generally well produced and whose colours are more realistic and less garish than some recent efforts by Collins to reproduce Marjorie Blamey's work.

Another collection of botanical jottings which is rather more tightly packed with interesting items of science and folk-lore, is Richard Mabey's book, *The Flowering of Britain* (Hutchinson, £9.95). The style is informal and will appeal to those who find information easier to accept and assimilate when presented in a chatty manner. No scientist should object to this whilst accuracy is retained. The historical and other tales in this book make very good reading and deserve to be read widely.

On the art side, Richard Mabey has found a very able associate in Tony Evans, whose colour photographs are superior to any I have previously seen in print. The atmosphere of his photographs is brilliantly conveyed by the careful setting of the plant subject in its surroundings. The unity of plant and habitat which results is reminiscent of the paintings of Marianne North and is equally striking. The camera may have replaced the brush in the equipment of the latter-day botanist, but the art of composition is still a rare gift: Tony Evans, in my opinion, has provided a new dimension to the art of botanical illustration.

Lords and ladies, by Marjorie Blamey

Peter D. Moore is Senior Lecturer in the Department of Plant Sciences, King's College, London. His most recent book is *The Mitchell Beazley Pocket Guide to Wild Flowers*, published in October of this year.

## Ornithology in art and art in ornithology

T. R. Halliday

IT IS one of the finer traditions of publishing that books on natural history have been illustrated by artists, some of whom have gained recognition within a wider artistic world. Three new books are richly endowed with the work of three of Britain's finest bird painters: Peter Scott, Charles Tunnicliffe and George Lodge. Peter Scott's autobiographical *Observations of Wildlife* (Phaidon/Cornell, £7.95/\$19.95) contains four chapters which deal with his major lifetime preoccupations as a painter and naturalist, as creator of the Wildfowl Trust, as a leading figure in conservation, and as a traveller and ambassador for the conservationist cause. Peter Scott himself draws attention to a feature of his work that some critics have deplored, that many of his paintings are just variations on the theme of a flight of birds against a dramatic sky. He attributes this to the demands of his market which have led him to paint to a "formula which guarantees sales but limits invention and innovation". Happily, this book bears testament to an artist of very diverse talents. The sketches from his diaries, which include studies of insects and fish as well as birds, are unexpected and exquisite. Peter Scott's text reminds us of the many important ways in which he has contributed to a greater understanding of nature and of conservation in particular, and it is understandable that his art has not been as varied and innovative as it might have been.

In contrast, Charles Tunnicliffe was an artist who devoted his entire life to his craft and Ian Niall's affectionate biography *Portrait of a Country Artist* (Gollancz, £10) contains vivid evidence of his many and varied skills. Here we find a rich variety

Charles Tunnicliffe at work, January 1952

of both subject matter and technique. Some of his oil paintings on unprimed cloth have a distinctly oriental flavour, while his woodcuts and etchings remind one of Durer. Sadly, Tunnicliffe's paintings sometimes seem over-posed and excessively pretty and have lost the life and vigour that he captured so brilliantly in his sketches. The basis of his work was a meticulous attention to detail which is best seen in his beautiful post-mortem studies of birds. The visual feast that his book provides is admirably complemented by Ian Niall's informative and interesting portrait of an exceptionally talented and self-effacing man.

*A Season of Birds* (Weidenfeld & Nicolson/A&W, £7.50/\$14.95) is a less successful book. The text consists of a diary kept by Jim Vincent in 1911 on the

wildlife of Hickling Broad, Norfolk, for which Edwin Montague commissioned illustrations from G.E. Lodge. The text is likely to be of interest only to the most ardent bird-watcher as much of it consists simply of a list of species seen on each day. Lodge's watercolours are reminiscent of Thorburn's work but are not nearly as successful at capturing the essential characters of their subjects. Lodge's reputation is mainly based on his painting of birds of prey and it is clear from this book that he was not nearly as good at portraying other kinds of bird.

T. R. Halliday is a Lecturer in Biology at the Open University and an author and illustrator of a number of books on natural history. His most recent volume is *Sexual Strategy*, published by Oxford University Press in October of this year.

## There was a young artist called Lear . . .

M. A. Ogilvie

*Edward Lear's Birds*. By Susan Hyman. Pp. 96. (Weidenfeld & Nicolson/Morrow: 1980.) £18.50, \$37.95.

THERE was an old man who said 'Hush!  
I perceive a young bird in this bush!'  
When they said - 'Is it small?' He replied -  
'Not at all!  
It is four times as big as the bush!'

Who else could have written that but Edward Lear? He did not invent limericks, but he certainly wrote some of the best there are, and illustrated them with his inimitable line drawings. To these add his nonsense verses ('The Owl and the Pussycat', 'The Dong with the Luminous Nose'), and one probably has the sum of most people's knowledge of him. This handsomely produced and lavishly illustrated book demonstrates just how restrict-

ed that knowledge is. The limericks and nonsense verses were not published until Lear was nearly 60, but by that time he had proved himself firstly as one of the finest natural history artists of all time, and then, abandoning this field before he was 30 because of failing eyesight and a lack of financial success, he became a highly talented landscape artist, producing several illustrated travel books from around Europe.

Susan Hyman, an American art historian, has concentrated on Lear as a natural history artist, and in particular on his bird portraits. And these were something special; Lear was an innovator and a precocious one. Ceasing formal education at 15, he began visiting the newly-opened Zoological Gardens in Regent's Park, sketching the birds and

animals. Within two years he was contributing drawings for the first visitors' guidebook, and the following year, when still only 18, he began work on a most ambitious undertaking, a series of 42 large (folio) plates of parrots. The most important difference between Lear and his contemporaries - and many of his successors - was that he drew from living birds. Instead of relying solely on the stuffed skin, with the resulting unnatural and angular postures on the plate, he worked in the Zoo, persuading the keepers to catch the birds for him to make detailed notes and measurements. Not content with painting more lifelike birds than anyone else, Lear also engraved his own stones for the lithographic reproduction, rather than handing over his plates to an engraver with the inevitable loss from the artist's

intentions. It is perhaps this, above all, which gives Lear's parrots their individuality and their character, as they peer out at one with beady eye and knowing look.

Several plates from *Illustrations of the Family Psittacidae, or Parrots* are reproduced here, together with, and adding greatly to the interest, sketches and preliminary studies, showing Lear's pencil notes on colour details and shape, instructions to the colourists, and charming vignettes of different postures. And, just once or twice, somewhat disparaging sketches of visitors to the Zoo who gathered round him to watch.

Lear contributed plates to books by many famous nineteenth-century naturalists, including Jardine, Selby, Eyton and Gould. This last-named ruthlessly exploited Lear, paying him little and even erasing his name from the plates and substituting his own. That Lear knew what was happening is perhaps revealed by a sentence in a letter written to Gould from abroad some years later: "I often think of

you when I see the large kites and falcons which are so numerous in the mountains where I have been residing".

The many sides to Lear's character and his varied talents are all brought out in this book. As well as the superbly reproduced colour plates there are many in black and white, including drawings from his nonsense books and a few from his period as a landscape artist. Lear was indeed a most remarkable man, and if, for the many, his memorial is made up of the limericks and verses of nonsense, then this book should certainly add to the few for whom Lear is quite simply the finest of bird artists.

In his own words:

How pleasant to know Mr Lear!  
Who has written such volumes of stuff!  
Some think him ill-tempered and queer,  
But a few think him pleasant enough.

*M.A. Ogilvie is a Research Officer at the Wildfowl Trust, Slimbridge, working on population and migration studies, and the author of several books on ornithology.*

## Photographic atlas of alpine flowers

G. Pontecorvo

*I Fiori delle Alpi.* By F. Rasetti. Pp.316. (Accademia Nazionale dei Lincei: Rome, 1980.) £19,500.

THIS monumental work, aimed at the naturalist, is the outcome of 20 summers of one man's intense botanizing throughout the Alps. The 572 excellent colour illustrations reproduced here — selected from some 8,000 photographs taken by the author in the wild — are one of the two major outcomes of that activity. The illustrations cover practically every species of angiosperm that has its altitudinal centre of distribution above the tree line. They include, as a most welcome but unusual feature, all 61 of the high-altitude Gramineae, Cyperaceae and Juncaceae; in fact the plates of these three families, usually neglected in illustrated field floras, are of an even higher quality than the rest.

The standard of the photographs and of their reproduction in this book disposes for good of the myth that preliminary identification from colour plates is easier if they are reproductions from paintings rather than photographs. The idea is that it is only in paintings that relevant diagnostic features can be emphasized and shown to best effect. Yet, of course, it all depends on the knowledge of the photographer and his ability to bring out what is botanically desirable. Rasetti includes an interesting discussion of this matter in a chapter on alpine plant photography.

The second upshot of the author's devoted and painstaking work on the Alpine flora lies in the longest and by far the most valuable chapter in his book. In

this, the botany of individual valleys and massifs is considered. For each, a short geological outline is followed by a discussion of the distinctive species of the area and their distribution. Becherer, in his *Führer durch die Flora der Schweiz* (Schwabe: Basel, 1972), has already attempted something of this kind, but limited to Switzerland and a few contiguous areas. Rasetti covers all of the Alps, north to south and from the Maritimes to the Schneeberg. Furthermore, in limiting himself to the alpine and nival plants, he has been able to deal with the subject much more extensively and in great detail. This section of Rasetti's book will be of great help to botanists, ecologists and amateur orophytologists who wish to know what grows where. Even the local wizard having a very detailed knowledge of the flora of his valley — and there are many — will find how and why his local haunts differ from those of the next valley.

It is a pity that a book with these two outstanding features — and many more minor ones — should be marred by a number of editorial shortcomings. To mention four: the format and weight are such that it cannot be carried for field identification, for which, presumably, the pictures were meant; the scale of a subject must be inferred by going from the picture to the index and then to the description of the species; there is no indication, with each picture, of time, altitude and locality; the description in great detail of the topography of the Alpine Range (with some new and valuable suggestions as to subdivision) is not supported by a sketch.

No doubt this major contribution to the

literature on the flora of the Alps will be translated into English and German, at least. These drawbacks can then be rectified. In the meantime, this Italian edition, besides being an essential acquisition for botanical libraries, will give much added interest to those carrying in their car Bacon's *Mountain Flower Holidays in Europe* (Alpine Garden Society, 1979).

*G. Pontecorvo retired in 1975 as a member of the research staff of the Imperial Cancer Research Fund, London.*

## Prayer for Shetland

H.N. Southern

*The Natural History of Shetland.* By R.J. Berry and J.L. Johnston. Pp.380. (Collins: 1980.) £8.50.

THE first author of this book is well known as a professional biologist; the second, since he is resident in Shetland and was previously the Nature Conservancy Council's representative there, has an intimate knowledge of the islands. Theirs is an unusual book because it is a mixture of a massive amount of raw data and an interpretation of some only of it, and because — in spite of this mixture — some important principles emerge from the illumination shed on the whole subject by the senior author.

Professor Berry has already shown in his previous book in this series — *Inheritance and Natural History* (Collins, 1977) — the significance, for tracking small-scale evolutionary processes, of studying the faunas and floras of archipelagoes. Shetland is such an archipelago, right on our doorstep, and he has used the information amassed, both by individual researchers and by the extensive surveys, funded by the government and the big oil companies, to further this interpretation of how the Shetland fauna and flora have evolved. The intensive investment in the extraction of North Sea oil has aroused fears of the possibility of disasters being inflicted upon a fragile environment and money has been provided to lay a base-line survey from which effects on the habitats can be measured. This survey of the fauna and flora has been a tremendous effort and its achievements can be judged from the full appendices to this book which comprise checklists for all of the groups of animals and plants that have been studied.

The text of the book is heterogeneous, as would be expected from the many authors who have taken part in the survey. Some aspects receive much fuller treatment than others (83 pages on birds and 9 on invertebrates, for example), again as might be expected. The chapters on vegetation and geology are solid stuff, though the maps illustrating the latter are reduced to the extent of needing a magnifying glass to

discern the details. Professor Berry, however, has made a great effort to produce some unification in this pot-pourri. His general introductory chapters, together with those he has written on the mammals (including Shetland man) and other groups (whose composition and distribution shed light, under his guidance, on what Darwin called "that mystery of mysteries — the first appearance of new beings on this earth"), have a vitality that leavens the lump.

The final chapters on the practicalities of

the extraction of the oil and the precautions that have been taken against disasters and on the potential problems which conservationists, and the Shetlanders themselves, have faced and are facing are cagey. We are left with the feeling that a good deal of what could be done has been done — as for the rest, we must just pray.

*H. N. Southern was formerly Senior Research Officer of the Animal Ecology Research Group in the Department of Zoology, University of Oxford.*

## Evolution of thinking on evolution

John Lawton

*Evolution for Naturalists: The Simple Principles and Complex Reality.* By P.J. Darlington, Jr. Pp.262. (Wiley-Interscience: 1980.) £12.75, \$27.50.

THIS is a lovely book — easy and enjoyable to read, outspoken, tart, philosophical and wise. In it, at all times and in whatever mood, Darlington displays a deep personal understanding of the living world, acquired by a life-time of study in the best traditions of scientific natural history, combining accurate observations with acute curiosity and a love for obscure corners of the living world, in his case carabid beetles.

It is not, or rather I did not find it, a straight-forward account of biological evolution written for interested laymen (that is, naturalists without a scientific training). Rather, it is an extremely personal view of evolution that might profitably be read by professional biologists and laymen alike.

It is perhaps trite, but it struck me forcefully whilst reading *Evolution for Naturalists* how human views of biological evolution have themselves evolved, and how they continue to do so. In the book, Darlington traces the early history of evolutionary thought, and explains carefully and precisely why Darwin's ideas are now favoured at the expense of others. Although the central theme is familiar, I was not aware of the clear and accurate statements of a theory of evolution by natural selection made by Scottish land-owner and forester Patrick Matthew, 28 years before the publication of the *Origin*. Even the best ideas are not always favoured by selection until the time and place are right!

Contemporary views on evolution range from the extremely primitive (of the "it doesn't happen" fundamental religious school), to the very sophisticated — with the whole gamut scrambling for attention, acceptance and success. Darlington has his own clear ideas about which should fail and which should succeed. There are the sound principles of the modern synthesis, carefully explained: sadly, whilst finding "great flaws in it", I doubt that President-elect Ronald Reagan would have the time or inclination to inform himself properly, even if he finds the book in his stocking on Christmas morning.

Amongst those who are better informed, Darlington himself sees "hopeful monsters" rampaging through the collective consciousness: most mathematical models of evolution, for example, he assigns firmly to this pedigree. I disagree; partly because I think he misunderstands some of the models, and partly because models force people to state their assumptions. They can therefore be useful, not monstrous, even if eventually proved wrong.

Other ideas he positions explicitly or implicitly at different points along the path of scientific appraisal and selection. Some, such as the strong group-selection theme permeating the book at all levels, are not to my taste either, but look set to enjoy a period of rapid growth and attention, despite strong initial selection against them. Those falling under the broad mantle of "sociobiology" have recently grown explosively, and are now subject to hard testing on many fronts; not all of this testing, in Darlington's opinion, is either ethical or scientific. Still more ideas are murmurings in the minds of a few: Darlington firmly believes, for example, that many adaptations are far from perfect, a heretical notion if ever there was one, but cogently argued.

Philip Darlington is retired. He wrote the book because he wanted to, not because he had to. He finds it neither far-fetched nor funny that Darwin might not be allowed a first-class college education today because he was bad at mathematics and worse at languages. He writes with affection about carabid beetles on mountain tops; the role of stone-throwing in the evolution of human co-ordination, perception and intelligence; and why evolution drives a progressive increase in organic diversity. And through all this detail, he writes directly, simply and with conviction. The book often made me pause; it sometimes made me cross; but above all it made me think again about evolution in all sorts of ways. If you are interested in evolution, and if you do not get *Evolution for Naturalists* in your stocking, buy it, or borrow the new President's — he won't have time to read it, though I wish he would.

*John Lawton is a Senior Lecturer in Ecology in the Department of Biology at the University of York.*

## Abroad migration

John Krebs

*The Mystery of Migration.* Chief editor Robin Baker. Pp.256. (Macdonald-Futura/Viking: 1980.) £13.95, \$29.95.

AT FIRST glance this appears to be a straightforward popular book about migration in plants and animals. However I suspect that many lay readers might find parts of the first two chapters sufficiently difficult to dissuade them from reading the rest.

The first chapter is an introduction consisting largely of an historical survey of ideas about bird migration. It includes two especially charming engravings from sixteenth- and seventeenth-century natural history books. One shows Swedish fishermen on the ice hauling in nets loaded with swallows; at that time it was thought that swallows spent the winter months

underwater. The other describes the ontogeny of a barnacle goose, showing how it develops from a goose barnacle through a series of gradual transitions in an illustration worthy of M. C. Escher.

After this the going gets a bit tough. Chapter 2 works through a series of definitions — lifetime track, familiar area, exploratory instinct, preferred direction, partial migration, navigation, orientation and pilotage — and develops some quite complicated arguments that would be more appropriate to a textbook than a popular account. An example is the section on the arbitrariness of various definitions of habitat. Although the diagrams here and elsewhere in the book are outstanding, the absence of labelling often leaves the reader confused — I struggled for some time, without success, to understand the graph about prairie dog migration on p.29.

The reward for persisting beyond the second chapter is a taxonomically arranged survey of migration (plants, invertebrates, insects, fish, amphibians and reptiles, various mammals and Man). The pages are full of interesting information and many are illustrated by some fine photographs and diagrams. My personal favourite is a photo of the trunk of a pine tree completely clothed in roosting monarch butterflies. The term "migration" is used in its broadest possible sense in the book so that it includes, in addition to "conventional" examples such as salmon, birds and butterflies, "migration" by potatoes or shallots as a result of forming swollen underground stems. The rationale for this extraordinarily broad definition is developed in Baker's earlier book (*The Evolutionary Ecology of Animal Migration*; Hodder and Stoughton, 1978). He argues that all forms of movement serve the same function (to transfer the organism from one site to another, even if sites are separated only by centimetres), so all should be labelled as migration.

The book has been written by a team of authors, and this may have contributed to some problems in continuity. For example, on p.32 the point is made that tracking radar allows an observer to follow individual birds of known species on their migration, while on p.135 we are told that radar studies are limited by their inability to distinguish between species of migrating birds. The possibility that pigeons might find their way home by infrasound is referred to in a general chapter on p.27, but warrants no mention at all in the section devoted to a detailed discussion of navigation and homing in birds on pp.161–165.

An inexperienced reader may find the text a bit difficult, but beginners and old hands alike cannot fail to admire and enjoy the photographs and — lack of labelling apart — the diagrams.

John Krebs is a Lecturer in Zoology at the Edward Grey Institute of Field Ornithology, Department of Zoology, University of Oxford.

## Companions for the fungal foray

Clark T. Rogerson

*Mushrooms of Western North America.* By R.T. Orr and D.B. Orr. Pp.293. (University of California Press: 1980.) \$6.95. *Mushrooms Wild and Edible.* By Vincent Marteka. Pp.290. (W.W. Norton: 1980.) \$15.95.

*Mushrooms of Western North America* is only the second guide to cover an area until now without much published information on its fungi. The area dealt with is the Rocky Mountains west to the Pacific Coast and from the Mexican boundary north to include Alaska. It is an introductory book written primarily for the novice in mushroom lore and identification, and treats only some of the commonest species. The introduction gives concise information on characteristics of fungi, seasonal occurrence and habitat, mycorrhizal associations, collecting fungi, and on edible, toxic and hallucinogenic species. The scientific nomenclature follows modern usage, about 30 of the larger ascomycetes, 100 non-gilled basidiomycetes and 200 or more gilled mushrooms being included. The descriptions are brief, appear to be accurate and include microscopic details. Information on edibility is given. Keys are given for the larger genera. Perhaps the major fault is that less than a third of the species are illustrated in colour, making the identification of the others by descriptions alone difficult for the beginner.

As an introductory field guide to the commonly found species, the Orrs' book will be useful and certainly should stimulate a greater interest in the fungi of the western United States and Canada.

Marteka's book, which deals with some common and easily recognized mushrooms, has several attributes that make it unique amongst the recent crop of mushroom books. First, it is arranged by seasons during which the mushrooms occur in the wild — not by a system of classification of those fungi included; second, it contains a wealth of information on folklore, first-hand field observations, environmental variations, case histories of experiences in eating mushrooms — much more than is typically found in books of this kind; third, it includes up-to-date and new information on preparing mushrooms for eating, both fresh and preserved, stalking wild and not so wild mushrooms in stores, growing your own mushrooms, and a good section on further reading. Only 30 species are treated in detail; they are described briefly but correctly, and all are illustrated with good colour photographs and additional black-and-white photographs and drawings are provided for some species.

The book is well written and organized: it really is enjoyable to read and browse through. While written primarily for

mushroom hunters in the United States, the choice of species will also make it useful in other parts of the world. For an introduction to the mushrooms and for a companion book to others which cover more species, it can be recommended to all who are interested in the subject.

Clark T. Rogerson is at The New York Botanical Garden, Bronx, New York.

## Love of hands

Bernard Wood

*Hands.* By John Napier. Pp.176. (George Allen & Unwin/Pantheon: 1980.) £12.50, \$13.95.

AS FAR as I am concerned there are two categories of books, "work" books and "non-work" books. I wish I could say that I read too many "work" books and too few "non-work" books, but the truth is that I don't read enough of either kind. Reviewing "work" books is simple in theory. They are either research monographs, symposium volumes or textbooks. The criteria are usually clear. Do they advance the subject? Are they comprehensive? Are they up to date? Mercifully, I am never called upon to review "non-work" books, but to take me past the first few pages they have to be entertaining, in the broadest sense, or illuminating, and preferably a combination of the two. John Napier's new book *Hands* straddles my literary boundary in an interesting way.

The book is presented in two nearly equal parts. The first deals with the structure and evolution of the hand. It sets out to explain what human hands are like, what they can do and how they came to be the way they are. The second part is devoted to four separate aspects of the hand. It covers how we use our hands, and considers tool-using and gestures. It also examines the forensic use of fingerprints, and "handedness". The author's aim is made clear in the first chapter. He wants to pass on to the reader something of the fascination and beauty of the hand, and he seeks to communicate some of the wonder we all feel when we come across any example of near-perfect harmonization of structure and function.

John Napier is less than fair to himself in the opening pages. He declares that he is

*The Image of Eternity: Roots of Time in the Physical World* by David Park, reviewed in *Nature* 288, 305; 1980, is available in the UK through Transatlantic Book Service, 24 Red Lion Street, London WC1, price £8.

infatuated with the hand. In my dictionary infatuation is defined as "an extravagantly foolish or unreasoning passion". I think his treatment neither extravagant or unreasoning, but, like all lovers, he occasionally fails to appreciate that what interests him may not always interest those not so closely involved, and vice versa. For non-anatomists, particularly, the section on morphology and evolution may be too dense, but elsewhere it is difficult to avoid making the charge that some subjects are treated too superficially. Again and again, just when I was beginning to be fascinated, the chapter was drawn rapidly to a close and my curiosity was left unsatisfied. The sections on fingerprints and handedness, for example, left me wanting more. The discussion of handedness hardly touches upon the neurological concomitants and there was no discussion of lateralization or speech. The neurological control of the hand is dealt with in the book, but very briefly. Too many questions are left unanswered. For example, does the brain deal with individual muscles, or whole movements? I was excited by the broader perspectives offered by his treatment of topics such as palimetry, the etymology of vernacular and anatomical terms, and the problems besetting a nail-brush designer! I am only sorry that he chose to explore so few of these general fields of interest.

On a more academic level, there are, of course some points of detail where I would take issue with the author, but these are few. I wonder why he discounts the pisiform as a carpal bone (p.35), and the course of the radial artery depicted in Fig.20 is an unusual one to say the least. Stone artefacts are found with the fossil remains of *Australopithecus* (p.113), and the mean brain sizes quoted for early hominids are confusing in their exactness (p.166). These minor points of detail, however, do not detract from a text which is generally of a high standard. The use of technical terms is sometimes uneven, and perhaps the publishers could have served the author better if they had encouraged him to include a glossary. I was disappointed, too, by the illustrations; they seemed predictable and rather dull.

For some years now there has been a steady buzz on the anatomical/anthropological "grapevine" to the effect that John Napier was writing a monograph on the hand. Many of us were eager to see Wood Jones's classic monograph of the 1920s updated. Unfortunately, while *Hands* will entertain a much wider audience, it will disappoint the professional fraternity. Not because it is not a good book in its own way, but because it is not the sort of book we were hoping for. I only hope that *Hands* will have whetted the author's appetite sufficiently for him to go on and produce the book we are still waiting for, and which he is particularly well equipped to write. □

Bernard Wood is Reader in Anatomy at The Middlesex Hospital Medical School, London.

## Flair for fossils

John C. W. Cope

*The Natural History of Fossils*. By C. R. C. Paul. Pp.292. (Weidenfeld & Nicolson/Holmes & Meier: 1980.) Hardback £15, \$37.50; paperback £6.95.

WHEN an experienced palaeontologist draws upon his knowledge and adds his own views on diverse aspects of modern palaeontology, the result promises to be interesting. When this is combined with a flair for imparting information to the uninitiated such as Dr Paul has, the result is a book which is informative, clearly presented and easy to read.

This is no textbook of palaeontology — nor does it profess to be such. Rather, it explains what palaeontology is concerned with — the uses of fossils, their palaeobiology, their ecology, their evolution and so on. Those who seek any sort of taxonomic treatment of fossils must look elsewhere.

In his discussion of each new concept, the author makes sure his readers are never left behind; there is careful exposition of many non-palaeontological topics, including "way-up" criteria, cyclothem, radiometric dating, palaeomagnetism, osmosis. Although, therefore, the book is readily accessible to the layman, it contains much that any aspiring palaeontologist should know.

From his introduction, the author goes on to discuss fossilization, with a useful review of trace fossils. Then follows treatment of sediments, fossil communities and associations. Consideration of faunal provinces and continental drift brings in palaeotemperature studies. The chapter on growth studies covers moult stages and modern work on growth-line studies of bivalves and corals. There is a useful

assessment of the adequacy of the fossil record and subjects such as the origin of life, evolution and the development of life on land are clearly discussed.

In his attempt to make the book comprehensible to the layman, Dr Paul has sacrificed some of the information which would make the volume more compulsory reading for undergraduates. Thus some diagrams are used to illustrate basic non-palaeontological concepts, whereas the space available and the subject really merit the imparting of additional and more advanced information through the medium of the diagrams. Incidentally, the reproduction of those diagrams included is not of the highest standard — how much the rough textured paper is responsible for this is difficult to judge.

There are 40 photographs which illustrate some of the subjects covered in the text. Their quality varies and they seem rather an afterthought — I do not feel that they contribute greatly to the book, but a layman unused to seeing fossils might well disagree.

In a book which is so stimulating and in which the author has clearly taken considerable care in presentation of his material, it is strange to find some words consistently spelt incorrectly. I found particularly jarring the mis-spellings of "Trias", "Lias", "Gault" and "isostasy".

The other titles in the *World Naturalist Series* suggest that this is primarily a book for the layman. As such, an introduction to modern ideas in palaeontology, it is a clearly presented exposition of the subject which deserves to succeed.

John C. W. Cope is a Senior Lecturer in Geology at the University College, Swansea.

## Geological tour de France

John Sutton

*Geology of France (with twelve itineraries)*. By Ch. Pomerol *et al.* Pp.256. (Masson: 1980.) £8, \$25.

GEOLOGY came into existence as a science in large part through the travels across France and Britain of some remarkable observers who were active more than 150 years ago. The founding fathers of geology are long since dead, but the rocks from which they learnt survive; with modern motorways we can cross in an afternoon what Smith, Murchison, de Beaumont and Cuvier took weeks to explore on horseback or on foot.

Geological traverses, though no substitute for painstaking mapping, can be great fun. Over there we see the hilltop of

Jurassic rock that Vercingetorix held against the Romans; here we find the Tertiary deposits overlying the Chalk from which all authentic Champagne is produced; and down there huge blocks of rock were displaced in the geological past to open the caves where Roquefort cheese now matures. This is what this book is about. It is not a geology of France as the English title wrongly states; it provides an account, prefaced by a summary of the geological structure of France, of what one can find of geological interest and much else besides on 12 journeys through the French countryside. "France géologique, grands itinéraires", as the original has it, puts the matter much better. Professor Pomerol assumes a knowledge of geology

on the part of the reader and uses technical terms freely. This and the remarkably bad indexes — erratic to the point of fascination — may restrict use of the book to those who already have a pretty good idea of what they are looking for and who know the jargon. This is a pity, for this guide is laid out in a way which could reward more than the committed geologist and could enliven a long journey across the country or contribute to an enjoyable leisurely holiday tour. Of the 12 itineraries, five radiate from Paris, though none reaches the Channel coast, so the English-speaking visitor descending at Charles de Gaulle airport fares better than the cross-Channel sailor. Other routes take in the French Alps, the Pyrenees and the Massif Central.

Instructions are specific, give route numbers, indicate good spots to park and are thoroughly practical. With their aid the

traveller can take in the general geology of the passing countryside and supplement this with stops to see outcrops at first hand.

This is a book to have handy in the car or to read by the Christmas fireside in anticipation or in retrospect. The translation is adequate but no more. With a little more trouble, fewer technical terms, an accurate index, a route or two for the traveller entering France at the Channel coast and some reference to relevant books in English the translation could be much improved. The Anglo Saxon critic must in fairness reflect that, Canada apart, geological guides in French to North America and Britain are rare birds. In this spirit we should welcome this migrant from the south and hope it reappears in finer plumage. □

John Sutton is Prorector and Professor of Geology at Imperial College, London.

## Seismology explained

Peter J. Smith

*Earthquakes.* By G. A. Eiby. Pp.209. (Heinemann Educational/Van Nostrand: 1980.) £7.50, \$14.95.

AT SCHOOL more than 20 years ago, I was pleased to come across a newly-published little book on earthquakes, written by G. A. Eiby of the Seismological Observatory in Wellington, New Zealand. Like most popular science books of the time — what few there were, that is — it was visually rather less appealing than the back of the local gasworks; and despite its dealing with the Earth, an international body if ever there was one, it had an irritatingly parochial emphasis in its chosen seismic examples, clearly reflecting the author's chief area of study. Still, earthquake-curious beggars in those days had little opportunity to be choosers as far as popular expositions were concerned and, for all its (really rather minor) faults, the Eiby of 1957 was a godsend to seekers of extra-curricula science.

By contrast, the 1967 revised edition of *Earthquakes* was a bit of a disappointment. It came at a bad time, of course, for never before had there been a period during which geophysics had undergone such rapid change. It must have appeared to Eiby at the time that the seismological advances of the early 1960s warranted an enlarged volume; but in retrospect it was not very wise to try to set down the state of knowledge about earthquake phenomena during a revolution in thinking in which seismics were to play an important part. Thirteen years on from there, however, things are quite different. Geophysics in general and seismology in particular continue to advance, but much more

slowly. It is now possible to take a more sober look at what the revolution of the 1960s and early 1970s threw up.

Those familiar with Eiby's two earlier volumes will be inclined to see the 1980 version as a third edition under a new publisher; and indeed there are some minor echoes of the past in chapter headings, the occasional diagram and the odd turn of phrase. In general, however, Eiby Mark 3 is really a new book — largely rewritten, glossier than its predecessors, fatter and with pages double the size. There is still a tendency to overemphasize the seismic position of New Zealand; but the context in which earthquakes may be discussed is now so much wider and more varied that this hardly matters. What does matter is that the end product, though obviously not scientifically complete in the sense that it records everything known about earthquakes, is comprehensive in that it covers authoritatively all those aspects of the subject likely to interest the non-seismologist.

So how does the new Eiby compare with its competitors? Very well. Although the layperson now has access to more material on earthquakes than ever before, most of it is tied up in wider ranging books on catastrophic phenomena — books with such exotic titles as *Disasters*, *Geological Hazards*, *Forces of Nature*, *Catastrophe* and *Earthquake*. Popular books devoted solely to earthquakes are still surprisingly rare. Of the two most recent volumes within this genre, the less said the better about *The Earthquake Handbook* by Peter Verney (Paddington Press, 1979). But much more importantly there is Bruce Bolt's *Earthquakes: A Primer* (Freeman,

Earthquake damage in Concepción, Chile, May 1960.

1978), a curiously underproduced book but splendid in content. Bolt's primer is likely to remain the natural resort of the non-seismological Earth scientist wanting to swot up on basic seismic matters; but the genuine layperson will probably find the 1980 Eiby the more attractive. □

Peter J. Smith is Reader in the Department of Earth Sciences at the Open University, Milton Keynes.

# To the planets and beyond

David W. Hughes

ASTRONOMY has always been a subject that can be tackled at many different levels. Diversity is one of its fascinations and is illustrated perfectly by the first two books in this year's Christmas collection. Both are about planets, both consider planets in considerable detail, but amazingly there is virtually no overlap between them.

Let us start with *Planetary Geology* by John Guest with Paul Butterworth, John Murray and William O'Donnell (David and Charles, £7.95). Half of the book is made up of photographs, half of text. I state this with some certainty because throughout the volume there are photographs from the United States National Aeronautics and Space Administration on the right-hand pages and a descriptive text on the left. The Moon, Mars and Mercury are dealt with in detail and there is a brief discussion of the features of Phobos, Deimos, Venus and the satellites of Jupiter. This format is most useful as you are invariably reading about surface features which are illustrated on the opposite page and which can be seen by a flick of the eye. The text stresses the physical and chemical processes that produce rocks and landforms, and also the evolution of planetary surfaces as a function of time. Each double-page spread covers a specific topic, a few *ad hoc* examples being crater rays, faulting, lava channels and tubes, graben, fretted terrain and so on. The book is fascinating; anyone interested in planetary science will find it most rewarding. Astronomers have suffered an invasion of geologists; our cohabitation is reasonably harmonious and this book will go a long way to make the relationship even more beneficial.

The systematic pattern of planetary exploration started with the ground-based telescope and progressed by using imaging systems on flyby and orbiting spacecraft, unmanned soft landers and, in the case of the Moon, a manned landing and return of samples. Paul Doherty, in his *Atlas of the Planets* (Hamlyn/McGraw-Hill, £6.95/\$16.95), has taken us back to the beginning and gives us a succession of drawings of the planets as seen by him through his 419mm and 254mm reflecting telescopes. Doherty derives an enormous satisfaction from planet-watching and this enjoyment and enthusiasm radiates from every page of his book. The great beauty of the planets is graphically described. This is an ideal book for the amateur astronomer and is a superb introduction to the problems, joys and possibilities of studying planets with small telescopes.

The next book takes us to the boundaries of the Solar System. *Out of the Darkness: the Planet Pluto* by Clyde W. Tombaugh and Patrick Moore (Stackpole: Harrisburg/Lutterworth, \$14.95/£7.95) describes one of the most painstaking

searches in the history of astronomy, the 25-year quest for Percival Lowell's "Planet X". Tombaugh gives an autobiographical account of his childhood on the farm, his first telescopes, his amateur telescope making, and the way he approached V.M. Slipher at Flagstaff and got a job at the Lowell Observatory. We then read of the planet hunting ("a slippery business" according to Tombaugh), the life at the observatory, the new 33cm objective lens, the hours of careful telescope guiding, the succession of 35.6 by 43.2cm photographic plates, the work at the Blink-Comparator, and the search for the ninth planet. The discovery of Pluto on February 18th 1930 and its aftermath is described vividly. After the excitement dies away, comes the slow realization that Pluto is not Planet X. The search continues. More plates, more stars, more comparisons, all to no avail. In the words of Kuiper: "What Tombaugh did not find out there was even more important than what he did discover". A Jupiter-like planet, if it exists, would have been detected out to a distance of 470 astronomical units, Earth could have been detected out to 100AU, other planets like Pluto do not appear to exist out to 60AU. If Pluto isn't Planet X and there are no more planets what did Lowell do wrong? How do we explain the perturbations of Neptune? This is a great story, told by a great astronomer and makes compulsive reading.

Beyond the planets we have the stars and again two completely different books aimed at the amateur star gazer. *Star Maps for Beginners* (Simon and Schuster; \$4.95, £2.95) by I.M. Levitt and Roy K. Marshall is a competent introduction to the splendours of the night sky which is now in its twenty-sixth printing. The kernel of the book is a sequence of monthly evening star charts

drawn for a latitude of 40 degrees North (Philadelphia, Denver, Peking and Madrid). The message of the book is "get outside and star gaze". For the more armchair-minded astronomer who specifically wishes to know the mythological associations of the constellations we have *The Constellations: How They Came To Be*, by Roy A. Gallant (Four Winds: New York/Scholastic: London, \$11.95/£5.25) published in late 1979. Gallant takes us on a legendary tour of the star lore of ancient civilizations and reveals the details behind the names of stars and star groups.

Turning to the more active amateur we have *The Pocket Guide to Astronomy* (Simon and Schuster/Mitchell Beazley, \$5.95/£3.95) by Patrick Moore and *An Amateur Radio Telescope* (Pachart Publishing: Tucson, \$6.95) by G.W. Swenson Jr. Moore's handy little book is ideal for the observer in a hurry. It has a full series of star and moon maps and a guide to the accessible double stars, variable stars, open clusters, globular clusters, nebulae and galaxies to be seen from both hemispheres.

Have you ever wanted to build your own radio telescope? If you haven't, read Swenson's book and you probably soon might; if you have, read it again and it tells you how. Swenson is thorough, all the information is there for the construction of an instrument relying on solid state circuitry. The book is made up of a series of articles originally published in *Sky and Telescope*. If you want to add words such as superheterodynes, baluns, yagis, impedance bridges and radio spectral pollution to your vocabulary it is just the book for you.

David W. Hughes is a Lecturer in the Department of Physics and Astronomy at the University of Sheffield.

## Cosmic contemplation

John Maddox

*Cosmos*. By Carl Sagan. Pp.416. (Random House: 1980.) \$19.95. To be published in the UK in spring 1981 by Macdonald-Futura, £12.50.

CARL Sagan is professor of astronomy at Cornell University and has for the past two years been working on a series of television films being shown, or to be shown, by English-language television stations on both sides of the Atlantic.

With the title *Cosmos*, the films add up to what the television people describe as a "blockbuster". The model seems to be that of Dr Jacob Bronowski's series *The Ascent of Man* — one man's view of an important theme.

This is very much the book of the television series. In a curious way, it reads like television. It is a series of purple passages linked together, so to speak, with magenta. Those who read the book — and there will be a great many readers, for it is a popular book — learn much less than they might have expected about the way in which the real Universe is constructed and much more than they need to know about Carl Sagan's own way of regarding the phenomenon of his own place in the scheme of things, nicely summarized by the opening sentences:

The Cosmos is all that is or ever was or ever will be. Our feeblest contemplations of the Cosmos stir us — there is a tingling in the spine, a catch in the voice, a faint

sensation, as if a distant memory, of falling from a height. We know we are approaching the greatest of mysteries.

As if in a distant memory, you can hear the television producer shouting "Fade music; voice over!"

The theme is thus that the Universe is very large, too large for the human imagination to comprehend. By great feats of imagination, humans (Sagan's word; mercifully, he is sparing with "Man") have nevertheless been able to comprehend a little. Yet the mystery remains.

The plan of the book is simple, but conditioned by its link with a sequence of film scripts. It is an explanation of the Cosmos, only partly a history of it. Sagan's special twist is his repeated statement of his well-known position on extraterrestrial life — there are living things out there somewhere but they won't look like plants or people.

For my taste, too many of the tales that Sagan tells have obvious origins in television's insatiable need for visuals. The Japanese legend of the Heike, the belief that the warriors killed in battles fought in antiquity now walk the sea bottom as crabs, is a nice way of illustrating how artificial selection works. I haven't seen the films, but would bet that Sagan and a film crew spent some time filming the carapaces of crabs in Japan.

As the title suggests, the book touches all the bases — indeed it does so economically, packing into its 400-odd pages an account of stellar evolution, galaxy formation, quasars, nucleogenesis, the origin of life, evolution and the question "Where will it all end?". In passing, Sagan gives thumbnail sketches of the contributions of people as different in character and time as Thales, Democritus, Leuwenhoek and Darwin to the progress of science.

Occasionally he uses the technique of lapsing into fiction: "Sometimes in my fantasies I imagine there was someone who thought like this . . .". There follows a soliloquy by a creature living in the "childhood of the genus *Homo*" on such matters as the economy (and the danger) of the hunter/gatherer society, the discovery of fire and the meaning of the stars.

I don't know if the stars are camp fires in the sky or holes in a skin through which the flame of power looks down on us. Sometimes I think one way, sometimes I think a different way.

Sagan's fantasy is fair enough, I suppose, even when he has this early hominid say that he would like to visit those camp fires in the sky. But the technique is a trick for making the tale more vivid, not for making it complete.

As an exercise in popularization, *Cosmos* courageously aims at the widest audience. Its readers will come away with a vivid impression that the Cosmos is an interesting place, the exploration of which has hardly begun, with a rich store of

anecdotal information about a variety of topics and with "a tingling in the spine". Some of the images are nevertheless unhelpful — is "an explosion in a spaghetti factory" the best image for the interior of a

cell, for example? I'm not sure, but I'd quite like to see how the film crew tackled that.

John Maddox is Editor of Nature.

Carl Sagan

## Heavenly images

Philip Campbell

*Galaxies.* By Tim Ferris. Pp.192 (Thames & Hudson/Sierra Club: 1980.) £20, \$75.

THIS book has been written for a popular audience, though professional astronomers — including galactic specialists — will probably derive some interest and not a little pleasure from it. In particular, it contains the most beautiful set of astronomical coloured photographs that I have encountered.

Tim Ferris, a science writer by profession, presents a clear and comprehensive discussion of the current understanding of his subject, working outwards, as it were, from our own neighbourhood. He discusses the structure and the constituents of our own galaxy — the stars, globular and open clusters, supernova remnants, interstellar clouds — before proceeding to the local group of galaxies and then to a more general discussion of galactic structure and evolution. Chapters are also devoted to interacting galaxies and to clusters of galaxies. The book ends with a brief and fairly standard introduction to big-bang cosmology.

In his style of writing, Ferris attempts to stimulate the reader's visual imagination to the full. A particular example of this is the

imaginary journey through the Universe with which he prefaces and parallels his chapters. Picturing the reader in a spacecraft constantly accelerating from the Earth at 1g, the author introduces the notions of relativistic time-dilation and cosmological space-time distances, his narrative occasionally tinged with wit.

At times, however, the style becomes obtrusive. Although uncluttered by references and mathematical or quantitative details, the text is scattered with similes and metaphors, at times laboured. Occasionally, astrophysical processes are described in the active present tense with anthropomorphized stars, for example, as protagonists. There is also a tendency to gush; the Andromeda galaxy M31, for instance, is described as "heart-rendingly" beautiful.

Such excesses apart, the informative text and superb illustrations make this an unusually fine book. The author makes full use of the large format (13" × 14") and the price of £20, though high, is for once not unreasonable. □

Philip Campbell is an Assistant Editor of Nature.

## Beauty in the tools of science

Silvio A. Bedini

*Antique Scientific Instruments.* By Gerard L'E. Turner. Pp.168. (Blandford/Sterling: 1980.) Hardback £3.95, \$12.95; paperback \$6.95.

SCIENTIFIC instruments were once the prized possessions only of Renaissance princes and prelates, acquired for their cabinets of curiosities. Generally they were masterworks of the goldsmith and engraver, more decorative than practical, for it was not until the early seventeenth century that instruments became functional as tools of measure and observation. It was with the emergence of the mathematical practitioners and the practical sciences of mapmaking, navigating, surveying and science teaching that the craft of the instrument maker developed

and flourished. With the advent of the scientific revolution other scientific apparatus and instruments of increasing precision were required, and played an important role in the advancement of the sciences.

Now, centuries later, these early instruments are eagerly sought by museums and collectors alike. In museum exhibitions they represent the work of important artists and craftsmen, and reflect the state of the sciences as part of national history. For the collector they are evidence of romantic aspects of the past and are tangible reminders of pioneering scientists. Instruments are sought and collected by some because of their beauty, by others through intellectual curiosity.

Until the past decade, few books had been published about instruments. Then, one by one, popular works started to appear, some describing and illustrating only pieces of the finest museum quality as examples of art, and others reflecting the role of the instruments as tools of the sciences. Only one or two have been designed to inform the collector.

In *Antique Scientific Instruments* Gerard Turner addresses himself specifically to the collector and has produced the first practical handbook on the subject. He has adopted the three broad categories into which the instrument-makers themselves divided their products — mathematical, optical and philosophical — and has further segmented the mathematical instruments into five groups based on their functions — astronomy and time-telling, navigating, surveying, drawing and calculating, and weights and measures.

The instruments categorized in each of these groups are briefly described as regards their history, function and physical appearance. Under optical instruments are included microscopes, telescopes and a whole range of optical "toys" such as mirrors, camera lucida, magic lanterns, zygoscopes, stereoscopes, kaleidoscopes and cameras. The philosophical instruments covered are basically teaching devices related to mechanics, magnetism, pneumatics, hydraulics, electricity, heat and meteorology. Each of the sciences to which each group relates is described in a short history. Also included are a chapter on "Practical Advice on Collecting", a useful bibliography for further reading, a list of museums having collections of instruments and a comprehensive index.

The author is particularly well qualified to produce such a book. The Senior Assistant Curator of the Museum of the History of Science at Oxford University, which contains what is considered to be the finest collection of scientific instruments in the world, Turner is internationally recognized as an authority on the subject. He

is the author of numerous articles and several books on the subject.

This handbook is equally useful for historians and students of science, as well as for the collector and the dealer in antiquities. □

## Doing time

Derek de Solla Price

*Greenwich Time.* By Derek Howse. Pp. 254. (Oxford University Press: 1980.) £7.95, \$24.95. *The Book of Time.* Consulting editor Colin Wilson. Pp. 320. (Westbridge Books/David and Charles: 1980.) £10.50, \$24.95.

SINCE the dawn of mankind time has had such a fascination for us that it is not much of an exaggeration to say that it has been the ultimate cause of Babylonian, Greek, and therefore of all modern science. Sheer workaday astronomical time has an exciting and crucial institutional history, and it is quite a feather in the cap of the British that Greenwich rather than Paris Observatory time became a world standard and the prime point of reference, not just for astronomers, but also for navigation and world geographers as well as the standard for the railroad age.

Derek Howse, an accomplished scholar and historical sleuth of the National Maritime Museum in Greenwich, has told the fascinating story of how it all happened in the international meetings and councils that had to deliberate the issues and resolve the intense international rivalries. The story of the International Meridian Conference, Washington 1884, is especially interesting for an analysis of the power play as convoluted as anything in the UN today. He has taken the matter right up to the present-day technologies that enable us to chide the wobbly earth for its non-uniform meanderings and institute "leap seconds" to correct it. A very pleasing book this is, written by somebody who really knows something. Not so with *The Book of Time*.

I imagine it all must have started with consultant editor Colin Wilson, a well-known novelist and author, being excited (as was J. B. Priestley) with the psychic mysteries of time and precognition. Unlike Priestley he did not write all of the book himself, but seems to have sold the publisher and editor on the idea of getting together a team of science writers to take on the merely scientific aspects of time, such

A double-barrelled air pump of about 1785, signed I.B. Haas Invt, By the King's Patent Made & Sold by J.H. Hurter, London.

Royal Swedish Academy of Sciences, Stockholm

as historico-theological, horological, biological, physical and geological. They are all covered passably well, except perhaps the one on the history of sundials and clocks which is trite, but one misses the passion of somebody who cares and really knows their stuff. Science writing is a tricky business and needs a certain genius to pull off with distinction, and evidently nobody cared enough to do more than get this book together as prescribed.

Since I cannot recommend it, let me say that if you are interested in the philosophical and psychological problems of time you might go back to an old but splendid thesis by M. F. Cleugh, *Time and its Importance in Modern Thought* (Methuen, 1937). And if you want something more modern than her book, you might wade through the scholarly chapters in the series *The Study of Time*, edited by J. T. Fraser and others of the International Society for the Study of Time (Springer-Verlag, Vol. 2 1975), or the fine and authoritative treatment by G. J. Whitrow, *Nature of Time* (Penguin, 1976).

Derek de Solla Price is Avalon Professor of History of Science at Yale University.

The Royal Observatory, Greenwich, with the time-ball on the east turret.

Mary Evans

## Mind-bending and the paranormal

David Davies

*Science and the Supernatural*. By John Taylor. Pp.180. (Maurice Temple Smith/Dutton: 1980.) £7.50, \$10.95.

THE late Chris Evans, a seasoned hunter of the paranormal, had one inflexible rule when in pursuit of unusual phenomena: do not pronounce on what you have seen for 24 hours — the excitement of the moment may cause you to say something that you would find difficult to retract later. Probably unaware of this rule, John Taylor went on television "live" in 1973 to act as (in his own words) "scientific hatchet man on Uri Geller". Before an audience of millions Taylor was bowled over by the metal-bending spectacular that unfolded in front of him (though he had apparently also seen it the previous evening) and has since devoted a substantial amount of time to pursuit of the paranormal.

In 1975 he published a book, *Super-minds* (Macmillan) which extolled the "Geller effect". He wrote "I have been convinced that such supernormal abilities [as Geller and some others generate] do actually occur . . . the total available evidence puts the Geller phenomenon truly into the class of the supernatural", and much more. In 1980 he tells a different story. Now, "the paranormal is totally normal. ESP is dead . . . I started my investigations with an open mind . . . on the evidence presented in this book, science has won". What manner of investigation,

what kind of evidence could cause such a complete about-face? For myself, in late 1973 I felt that maybe there really could be something that merited examination by scientists. Three years later I felt it was probably all bunk. This was a journey of steadily growing awareness that magicians have remarkable "paranormal" deceptions up their sleeves (as James Randi has continually demonstrated), that children are not averse to playing quite sophisticated tricks on grown-ups — particularly if it gets them attention — and that scientists, whilst detached observers of experiments under their own control, may have no special abilities in observing the much more complex goings-on that generally surround allegedly paranormal happenings. In short I learnt a lot about people.

John Taylor's route was very different. He argued that electromagnetism was the only possible explanation for unusual phenomena and therefore that electromagnetic measurements should be made and electromagnetic theories sought. And when nothing turned up (except from some fairly simple electrostatic explanations of the odd phenomenon) Taylor found himself forced to the conclusion that the phenomena were without substance. It is, for my taste, a circuitous and intellectually unsatisfying argument. For all that I believe his final conclusion is correct, I'm not sure that one is allowed to pronounce a subject dead simply because one's own

intellectual skills and measuring equipment cannot come to grips with it.

The consequence of Taylor's conclusion that the paranormal does not exist is that people have deceived him left, right and centre. But this book, which wanders anecdotally through the whole gamut of strange happenings, barely comes to grips at all with the question of why some people deceive and why others are deceived. Indeed, Taylor, now back in the anti-paranormal camp, is hard and unforgiving of those who adduce the sort of evidence which until recently he would have taken seriously: "There is a high level of gullibility where seeming inexplicable events are concerned. Even apparently sober people appear to become very naive after witnessing something in the heavens [UFOs] which they cannot readily explain". Five years ago, Taylor himself was writing: "Puharich has observed Geller enter an unidentified flying object . . . unhappily the film cartridge containing the essential record of this event was lost, having dematerialised within a few minutes". It surely needs more than a few null results from electromagnetic equipment to reverse positions quite so dramatically.

David Davies was Editor of Nature from 1973–1979. He is now director of Dartington North Devon Trust, a charity dedicated to rural development.

## Avian delights: on the wing and on the water

John Andrews

PROFESSIONAL ornithology in the UK is fortunate in benefiting from substantial skilled amateur assistance and from a rapidly expanding public interest in birds and their place in nature. One result of this has been a steady increase in the funding available for research to determine the effects on birds of land-use changes and of individual development schemes. This is certainly the case with work on waders. Moving south from their breeding grounds each autumn, many species overwinter in our relatively mild, unfrozen estuaries, which are subject to threats from a great diversity of uses and abuses. In *Waders* (Collins, £9.50), Professor W.G. Hale draws together current knowledge on the biology of those species which occur in Britain, much of it either collected by amateurs or as a response to pressure from them, expressed through the conservation organizations.

Commencing with a general introduction to the species concerned, the author moves on to deal with habitats and adaptations, geographical distribution, mortality and evolution, breeding biology, migration and various aspects of wintering

ecology, including the important subject of estuarine carrying capacities which arises wherever a public inquiry asks the question "why can't these birds go somewhere else?" The author is particularly known for his own work on redshank, largely undertaken on the Ribble saltmarshes, themselves recently threatened by a scheme to embank and convert them to arable farmland. Complete with a substantial bibliography and index, the book is illustrated and presented to the high standard one expects from the *New Naturalist* series.

It is pleasing to find another publishing house aiming to produce works of similar quality. Some years ago Hamlyn produced a volume which came up to *New Naturalist* standards but was a little more adventurous in presentation and ventured outside the latter's self-imposed limits of the United Kingdom to look at birds of prey worldwide. Now they have produced a volume on *Seabirds: Their Biology and Ecology* (£7.50, \$14.95) written with evident enthusiasm by Dr Bryan Nelson of Aberdeen University and illustrated generously throughout the text not only with well-chosen colour and black-and-white photographs, but also with delightful drawings by John Busby. The author has put together an authoritative summary of the biology and ecology of seabirds worldwide in a relaxed and fluent style, without wasting words or taking the non-scientist out of his depth. After a general chapter which indicates the diversity of seabird species and of their biology, the reader is led to consider the problems and opportunities presented by their vast, rich and complex habitat, the oceans of the world. From there, the book turns to food resources and feeding methods and thence to breeding behaviour and biology, concluding with sections on movements and distribution, populations and human impact. Unlike waders, seabirds are known mostly at their breeding sites and so this aspect of their lives occupies about half the book as against one-twentieth of the text of *Waders*. All concerned deserve congratulations for producing a thoroughly enjoyable and instructive work at such a relatively modest price.

Because of their importance as quarry, geese have always attracted a good measure of interest in their distribution and numbers. Latterly, linked to a growing concern for their conservation, they have enjoyed a relatively large share of the bird research effort in both Europe and North America. For the last 13 years Dr Myrfin Owen has been working on goose ecology at the Wildfowl Trust and in *Wild Geese of the World* (Batsford, £15) he presents and discusses current knowledge of all 15 species and 23 sub-species. The first third of the book is occupied by species' accounts and the bulk of the very readable

text is reserved for discussion of social behaviour, movements and migration, summer and winter biology, population dynamics, and conservation and exploitation. Thanks to the research effort devoted to them, some aspects of the complex biology of geese are now understood, but much still remains to be worked out and the author ventures some stimulating speculation in these areas. The book is helpfully supplemented by line illustrations, accurate colour plates and a substantial bibliography.

Knowing what to leave out of any book is part of the art of writing and one most relevant to any book on general bird biology where there is a risk of taking all the information available, much of it pre-digested by other authors, and piling it into convenient heaps too large and generalized for comfort. The basic form of *Birds* (W.H. Freeman; hbk \$17.95, £10.60; pbk \$8.95, £4.90) is much the same as usual — geography, flight, migration and navigation, evolution, behaviour, physiology and song. The refreshing difference is that, while each is introduced by a crisp article summarizing the topic in very broad terms, there then follow several papers by different authors, focusing on one or another aspect of the subject. The papers — 25 in all — are selected from about 40 which have been published in *Scientific American* over the past 30 years. Despite the time span in which they were written and the many different authors, the whole book works well. It is surprisingly cohesive and easy to read.

Another imaginative, but less successful venture into natural history publishing is Derek Bromhall's *Devil Birds: The Life of the Swift* (Hutchinson; hardback £8.95, paperback £5.95). In 1948 Dr David Lack installed swift nest boxes in the roof of the tower of Oxford University Museum of Science to accommodate what has since become the best-known swift colony in the world. In 1975 Derek Bromhall decided to make a film of the same colony and this book is set against the background of its making. Swifts are fascinating birds by any standards. At about six weeks the youngsters leave their dark nest, plunging into sunlight and space at the beginning of a flight which may last for three years or more before they return to the colony to breed. Adapted to life on the wing, feeding on aerial plankton, swifts casually undertake movements of hundreds of kilometres to avoid bad weather, sleep in the air and sometimes even mate in flight. The fairly short text is an unpretentious and readable presentation of interesting information but the book is irritatingly over-illustrated by photographs many of which are of poor quality and add nothing to one's understanding of the subject. A pity because the idea is a good one and any attempt to

## GUIDE TO AUTHORS

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

**Manuscripts** may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible:  $\exp(a)$  is preferred to  $e^a$  if 'a' is more than one character.

**References** are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

**Artwork** should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

*Nature's* publishing policy is outlined in 258, 1 (1975) and 264, v, 11 Nov. (1976).

## Awards

**Georges Köhler** (Basle Institute of Immunology) has been awarded the Albion O. Bernstein M. D. Prize for 1980 by the New York Medical Association.

**Dr Günther Ohloff** (Switzerland) is to receive the 1980 Hackforth-Jones Award for his work in perfumery chemistry.

**Dr Arthur Kornberg**, (Stanford University) has been awarded the 1981 Forteza Gold Medal by the Institute for Cell Research of the Caja de Ahorros of Valencia, Spain.

In the Chemical Writers' Awards BASF in association with the SCI have announced that **Peter Grange** (technical editor of *British Plastics & Rubber*); is Chemical Writer of the Year; **Mike Hyde** (editor, *Chemical Insight*) is Chemical Reporter of the Year; **John Murphy** (editor, *Plastics Industry Europe*) is Chemical Application Writer of the Year; and **David McDonald** (editor, *International Pest Control*) is Agrochemical Writer of the Year.

## Appointments

**Trevor W. Cole** has been appointed the P. N. Russell Professor of Electrical Engineering at the University of Sydney, Australia.

**Dr J. L. Hall**, reader in plant physiology in the University of Sussex has been appointed to a Chair of Biology in the University of Southampton with effect from 1 April 1981.

New members of the Directorate of the CERN Laboratory in Geneva include: director general, **Professor H. Schopper**; research directors, **Professor R. Klapisch** (France), **Dr Erwin Gabathuler** (UK); technical director, **Dr G. Brianti** (Italy); LEP Project Leader, **Dr E. Picasso** (Italy); administrative director, **Dr R. F. Heyn** (Netherlands).

## Meetings

13-16 April, **88th Health Congress**, London (Royal Society of Health, 13 Grosvenor Place, London SW1, UK).

29-30 April, **Gauge Theories of the Fundamental Interactions**, London (The Royal Society, 6 Carlton House Terrace, London SW1, UK).

4-7 May, **Emerging Environmental Solutions for the Eighties**, Los Angeles (Institute of Environmental Sciences, 940 East Northwest Highway, Mt Prospect, Illinois 60056).

6-7 May, **Monoclonal Antibodies and Ultrasensitive Immunoassay in Human Diagnosis and Monitoring of Therapy**, Gardone Riviera (RIA 81, Fondazione Giovanni Lorenzini, Via Monte Napoleone, 23, 20121 Milan, Italy).

8-9 May, **Calcitropic Hormones Methods and Clinical Applications**, Gardone Riviera (RIA 81, Fondazione Giovanni Lorenzini, Via Monte Napoleone, 23, 20121 Milan, Italy).

10-16 May, **The Structure and Development of the Greenland — Scotland Ridge**, Bressanone (Prof. Svend Saxov, Laboratory of Geophysics, Aarhus University, Finlandsgade 6-8, DK-8200 Aarhus N, Denmark).

14 May, **Ores in Sediments: Mineralising Fluids**, London (Geological Society of London, Burlington House, London W1, UK).

11-15 May, **Remote Sensing of Environment** Ann Arbor (Ann Arbor Conference & Visitors Bureau, 207 East Washington St, Ann Arbor, Michigan 48106).

14-18 May, **Reproductive Immunology**, Banff (Dr T. G. Wegmann, Division of continuing Medical Education, 12-103 Clinical Sciences Bldg, University of Alberta, Edmonton, Alberta, Canada T6G 2G3).

18-22 May, **Ground based Spacecraft Flight Dynamics Operations**, Darmstadt (R. E. Münch, esoc, Robert-Bosch-Strasse 5, 6100 Darmstadt, FRG).

19-21 May, **Telecommunications Energy Conference**, London (IEE, Savoy Place, London WC2, UK).

1-13 June, **Methods of Immunological Research and Diagnosis**, Buffalo (James F. Mohn, The Ernest Witebsky Center for Immunology, State University of New York at Buffalo, 210 Sherman Hall, Buffalo, New York 14212).

2 June, **Geothermal Studies**, Southampton (Geological Society of London, Burlington House, London W1, UK).

8 June, **High Pressure as a Reagent and an Environment**, Washington DC (Dr Robert S. Shane, 7821 Carreigh Parkway, Springfield, Virginia 22152).

10-12 June, **Leukotrienes and Other Lipooxygenase products**, Florence (Fondazione Giovanni Lorenzini, Via Monte Napoleone 23, 20121 Milan, Italy).

16-17 June, **Chromatography in Biochemistry, Medicine and Environmental Research**, Venice (Dr A. Frigerio, Mario Negri Institute for Pharmacological Research, Via Eritrea, 62-20157 Milan, Italy).

18-19 June, **Mass Spectrometry in Biochemistry, Medicine and Environmental Research**, Venice (Dr A. Frigerio, Mario Negri Institute for Pharmacological Research, Via Eritrea, 62-20157, Milan Italy).

## New ventures

A new service has been launched by Harwell which makes the Laboratory's neutron beam facilities available to industry for research into materials problems. The service, based on Harwell's DIDO and PLUTO materials testing reactors, provides a range of techniques — radiography, crystal diffraction, small angle scattering and vibrational spectroscopy — for the investigation of materials properties. Further details from: Peter Schofield, Materials Physics Division, AERE Harwell, Didcot, Oxon OX11 0RA, UK.

A new company Merseyside Laboratories has been formed to manufacture and distribute peptides, amino acid derivatives, resins, anti-sera and reagents and catalysts for asymmetric synthesis. Merseyside Laboratories also has a custom peptide synthesis service. This company is the UK and European distributor of peptides manufactured by Peninsula Laboratories, California. Further information from: Merseyside Laboratories, PO Box 62, 21 Aston Court, Kingsland Grange, Woolston, Warrington WA1 4SL, UK.

London-based Scientific and Technical Book Services Ltd have acquired world distribution rights in English for two Chinese scientific journals. *Science in China* (Scientia Sinica) and *Science Bulletin* (Kexue Tongbao). Further information from: Jennifer Clarkson, Gordon & Breach, 41/42 William IV St, London WC2N 4DE, UK.

The *Journal of Psychophysical Systems* commences publication shortly, with the object of promoting research into the behaviour of systems in which the presence of psychic factors cannot be ignored. Further information from: Prof. D. F. Lawden, Dept of Mathematics, University of Aston, Gosta Green, Birmingham B4 7ET, UK.

Elsevier announces a new bi-monthly publication *Applied Catalysis*, an international journal devoted to catalytic science and its applications. Sample copies from: Elsevier Scientific Publishing Company, PO Box 330, 1000 AH Amsterdam, The Netherlands.

11 December 1980

# Code of conduct for national academies

The national academies of science throughout the world are a mixed bag. Some of them, and certainly the oldest among them, exist more or less by accident. The *Accademia dei Lincei* began in 1603 as a kind of club for cultivated Roman noblemen interested in the doings of those scientists whom they chose to maintain by patronage. The Royal Society in London, also very much a club of enthusiasts, nevertheless won the blessing of Charles II on the strength of its promise that science might help with some of the British government's problems, how most effectively to navigate the oceans for example. Unlike the *Lincei*, the Royal Society has had the good fortune of an uninterrupted history. Elsewhere, national academies have more formal origins. The National Academy of Sciences in the United States, now just over a century old, was set up by the US Congress explicitly to provide advice on scientific and technical questions. Since then, it has become the custom to build in an academy to every new constitution — this, for example, is how the Academy of Sciences of the USSR came formally to be responsible for the administration of a substantial part of the Soviet government's research and development. With the passage of time, the notion has taken hold that national academies, while remaining clubs in the sense that only the membership has a voice in its succession, also have important functions in relation to their national governments.

On the face of things, this relationship is anomalous. What benefits can governments hope to derive from relationships with self-perpetuating societies of scientists? And why should clubs of scientists, having elected each other on the grounds of their achievements in research, then look for a special influence in public affairs for which their scientific work will not have prepared them? These are the questions implicit in Lord Todd's address to the anniversary meeting of the Royal Society last week, at which his five year stint as president of the society came to an end.

Breaking with the customs of gentility that mark these occasions, Todd openly complained that his immediate predecessors had spoiled the relationship between the society and the British government. "From 1950 under three successive presidents", he said, "the society gradually lost influence and drifted away from matters of public policy." The references are to Lord Adrian, Sir Cyril Hinshelwood and Lord Florey, presidents in succession between 1950 and 1965. Todd's analysis is fair, although, in Florey's case, the decision to disengage from government was deliberate. (Instead, Lord Florey tried, without much success, to interest the Royal Society as a whole in matters such as the rate of population growth.) Todd was also right to complain last week that the Royal Society was, as a result, far less able than it might have been to influence the upheavals of the early 1960s — the Robbins expansion of the universities ("ill-considered"), the abolition of the Advisory Council on Scientific Policy, the separation of technology from science and the transfer of the latter to the Ministry of Education (now the Department of Education and Science). But from 1965 until 1970, according to Lord Todd, Lord Blackett's personal commitment to the then new Labour government compromised the independence of the Royal Society and thus further diminished its influence.

The issue here is complicated. Blackett's own influence on the Labour government's policy was immense. Respected as he was by the then Prime Minister, Mr (now Sir) Harold Wilson, Blackett lent his support to some of the favourite policies of the Labour government, for example the Industrial Reconstruction Corporation which acted as midwife to the string of injudicious

industrial mergers of the late 1960s. There can never have been so influential a president. The fact that many of the then Labour government's policies are now recognized to have been mistaken is presumably irrelevant to Todd's implicit definition of how an academy should conduct itself. To be identified with government is to be compromised, even if government policy shows the wisdom of Solomon. But to offer independent advice and even help is not merely common patriotism but in the interests of science and its effective application. This, however, is not an easy balance to strike, if only because of the notorious reluctance of governments to take advice that does not suit them.

Lord Todd's account last week of his own presidency shows what the problems are. He made no secret of his fondness for the Advisory Council on Scientific Policy, which used to publish an annual commentary on the evolution of government policy on subjects as varied as the recruitment of scientific manpower and the conditions (always parlous) of the national scientific libraries. The modern equivalent is the Advisory Council on Applied Research and Development which puts out reports on subjects such as the economic and social consequences of the microprocessor. Todd said last week that the existence of this committee, like the presence of a scientist in the part of the Cabinet Office known popularly as the "think tank", owes something to his own intervention in his role as president. One obvious snag is that, in these respects, the Royal Society has been concerned with mechanisms and not with content and that the arrangements devised fall far short of what Todd himself said last week that he would prefer — the separation of the research councils from the Department of Education and Science and the restoration of the old advisory council. Another, perhaps more serious, difficulty is that the Royal Society has no means by which it can reach a corporate opinion on any substantial issue of public policy. Although, in the past few years, there has been a modest growth of the society's efforts at providing government and parliamentary committees with written evidence on questions such as secondary education or the environment, the process is slow and the outcome is often a muffled recommendation, not a clarion call. The Royal Society would be unable, even if asked, to arrive at anything like a corporate view on, say, government policy on nuclear power stations or whether manufacturers of drugs should in future be liable for side-effects even if there are no known ways of telling in advance what these might be.

To be fair, in this respect even the United States academy is no better off. Congress may commission studies of the hazards of low-level radiation or of climatic change, and the academy will dutifully recruit a panel to do the work without committing each of its members to the conclusions. But neither Congress nor the Administration would welcome the academy's unsolicited opinion on, say, the proper organization of federal research agencies or on the zany procedures followed by Congress in settling the annual research budget. It may be luck for all concerned that the academy would be likely to have as many conflicting opinions on such questions as it has members. Thus even the United States academy, corporately, is not nearly as influential as it likes to think. Its members, especially its president, may often be powers in the land, but almost always on personal grounds — and by personal means, back-slapping and arm-twisting, if it comes to that.

How, then, should academies set out towards Todd's two domestic goals — "to protect and encourage science in all its aspects" and to advise on and help with bringing science and

technology "fully to bear on the formulation of national policy"? The first need is that they should acknowledge their own limitations. They cannot hope too often to bite the hands that feed them without being fed less well. Yet there are some issues on which the academies' unprompted advice would be helpful and even welcome. Both in Britain and in the United States, there is thus a need just now for an independent examination of the relationship between academic research and commercial exploitation. Harvard's problems with genetic manipulation (see *Nature* 4 December) are likely to crop up elsewhere, and in

different fields. The academies are better placed than either universities or governments to say what should be done, but they have been slow to devise an agenda for discussion. (Are they, by any chance, afraid of offending their members?) Similarly, there is an urgent need (and not only in Britain and the United States) for an independently formulated policy on higher education in science, and on the problems of professional people thrown on the scrap-heap before retirement age because of chopping and changing of government policy. If they chose, the academies could be more directly influential than they are.

## Further nonsense on product liability

The United States Supreme Court, which does not often make an ass of itself, handed down a decision in October which will already have denied sleep to a host of manufacturers, especially to pharmaceutical manufacturers. The Supreme Court had been asked to rule on the legality of a decision made last March by the Supreme Court of California in the preliminary stages of a suit for damages. Two Californian litigants were suing because of the congenital damage they had suffered because their mothers took diethylstilbestrol during pregnancy. The original claims were faulty in that the plaintiffs did not specify the manufacturers of the diethylstilbestrol from whom they sought damages, but the Californian court helped out by suggesting that any damages eventually awarded might be shared among the suppliers of diethylstilbestrol in proportion to the various manufacturers' shares of the Californian market. The United States Supreme Court has now confirmed that this device is permissible, at least at this early stage. Whether the original suit (which has not yet been heard) will succeed, and will then survive the inevitable circuit of the appeal courts, remains to be seen. But the law on product liability, more stringent in California than elsewhere, is in danger of being made a nonsense. It also promises to be a serious impediment of innovation.

The issues are not complicated, even though the law may be. A manufacturer designs a product, say a mousetrap, sells several copies to the public and makes himself a profit in the process. As time goes on, the mousetraps are used to catch a host of mice, a benefit to the purchasers. But, sooner or later, a clumsy user will impale a finger on a piece of metal or have it broken because the trap goes off prematurely. Who, then, is to blame? In the old days, the law in most countries coincided with commonsense. A person buying a mousetrap intended to injure mice who managed to injure only himself had no cause to sue the mousetrap manufacturer. If he did so, the manufacturer would have been able to plead "contributory negligence" or something of the sort, and the only beneficiaries would have been the lawyers. In future (but already in California), the hapless mousetrap manufacturer will not be able to rely on that defence. First, he must design his mousetrap so that foreseeable accidents cannot take place. Mousetraps that cannot catch fingers will be more expensive and may be less efficient at catching mice, part of the price of product liability. What will keep manufacturers awake at night, however, is the fear that their designers have not thought of every accident. Is there a risk that in emptying the trap of mice, an innocent user may suffer some unsuspected damage? May he contract cancer, for example? For, if that happens, the manufacturer will be liable for damages under the law of strict product liability.

The Supreme Court's decision shows that the vigorous application of this principle offends against natural justice. If all manufacturers of diethylstilbestrol are to be joined in the suit in proportion to their sales revenue in the 1950s from the synthetic hormone, the implication is that no aspect of their behaviour can diminish their share of the liability. Yet some may have been more diligent than others in seeking out unwanted side-effects. Some may have made more profit than others. And some may have gone out of business, leaving the others to carry a greater share of the liability. The reasons why the drug manufacturers are especially

alarmed is clear — identifying unknown side-effects is an open-ended problem, for which reason it seems unfair that virtue is no defence. Strict product liability thus seems inequitable as between individuals. It is too soon to know how many drug manufacturers will turn to making mousetraps because the risks are better known, but strict product liability is a deterrent from doing anything for the first time. The community at large will not in the long run benefit.

This is the manufacturers' case against strict product liability. The other side of the argument is also telling. In the past thirty years, all kinds of manufactured products have turned out to be less safe in use than their salesmen promised. Motor cars have caught fire without warning, or have careered off highways. Aircraft have fallen from the skies unexpectedly, for reasons attributable (with hindsight, easily enough) to faulty design. Electrical appliances have electrocuted their users. And drugs have caused damage as well as bringing benefit, often in the most tragic ways. The wave of product liability legislation springs from the fund of reasonable grievance by innocent consumers against manufacturers who have frequently been slipshod in design or even guilty of telling lies. Manufacturers should not think their troubles will go away spontaneously. In Britain, for example, in the past three years, one royal commission (the Pearson Commission) and two law commissions (one for Scotland, one for England and Wales) have advocated the principle of product liability. How is a line to be drawn between the interests of manufacturers and consumers?

In Europe, the issue is lively just now because of the draft directive on product liability promulgated by the European Commission, and likely to compel national legislation in the next few years. The question is obviously within the interest of the European Commission, for without common legal principles, member states could use product legislation as a way of favouring their own manufacturers. But what should be the common standards? In the past few weeks, the British government (which accepted the principle of strict liability two years ago) has said that it will press the European Commission to allow as a defence by manufacturers the plea that a new product is as safe as the "state of the art" allows. The diethylstilbestrol manufacturers of California would be delighted with such a lifeline in their own case, but it is unlikely to satisfy either the European Commission or European consumers. The snag is that such a defence does not provide manufacturers, either collectively or singly, with an incentive for investing in research and development intended to improve the safety of their products. Indeed, used mischievously, the state of the art defence could become a refuge for the complacent. But is it entirely beyond the lawyers' wit to design a form of words that would allow a manufacturer to defend himself, if something goes wrong with a new product, by pointing to steps prudently taken in the research laboratory to investigate the safety of what he makes? Unless some such device can be found, there is a serious risk that innovation, especially adventurous innovation, will be inhibited. Whatever happens, the drug industry is bound to feel unfairly put upon because its new products have to be tested under government supervision. Should not such a procedure in itself be a defence against a product liability suit?

# Congress shares out patent licences

## Universities, business, given wider rights

Washington

After several years of intensive lobbying, US universities have persuaded Congress to pass a bill which will enable them to profit directly from the commercial exploitation of any research carried out with federal funds.

The bill was passed hurriedly by both the Senate and the House of Representatives in the last days of the session, and is expected to be signed into law by President Carter before the end of the month.

It makes uniformly applicable across all government agencies an arrangement which universities are already able to make with some departments, giving them the right to license patents arising from the work of federally-sponsored scientists provided that all profits made by the university are ploughed back into teaching or research.

The bill has been strongly advocated by university administrators and patent officers, who have claimed that it will reinforce their efforts to get the results of research onto the marketplace. The bill does not, however, go as far as some would have liked, as it awards patent rights only to small businesses and non-profit institutions, and is therefore not applicable to large companies which receive federal research support.

An alternative version of the bill originally passed by the House of Representatives included comparable coverage of large business. But this provision was fiercely opposed in the Senate, where several members argued that it would result in a "massive give-away" of public resources (*Nature* 6 March 1980).

Rather than prejudice the agreement between the two legislative bodies which is necessary before a bill can become law, members of the House agreed to limit the scope of the bill. They have, however, promised that there will be further attempts to introduce additional legislation covering large companies when the new Congress convenes next year.

In the past, the rights to any patent arising from publicly-funded research have remained the property of the federal government, on the basis that the results of research should be made available to anybody who wants to use them, and that any profits should go towards covering the costs of the original research.

With nobody actively pushing the commercial development of the patents, however, the take-up has been small. Of

the 30,000 patents that have been awarded to the federal government, no more than 5 per cent have been licensed.

In an attempt to give universities a greater incentive to find or create markets for their research results, both the National Science Foundation and the Department of Health, Education and Welfare have recently permitted research institutions to enter into an Institutional Patent Agreement.

Under such arrangements, which have been agreed with more than 30 leading US universities, the institution is allowed to retain patent rights provided that it can present evidence that it will press vigorously to license such patents as it is awarded. (Such an arrangement, for example, has given Harvard University the rights to the results of recombinant DNA research carried out with funds from the National Institutes of Health.)

Even this arrangement has come under fire from some scientists. Two years ago, for example, Professor Joshua Lederberg, now president of Rockefeller University in New York, wrote to a Senate committee suggesting that universities should stay out of the patent business, and suggesting some form of holding institution along the line of Britain's National Research Development Corporation to which patent rights should be allocated.

But support for expanding the principle to cover all federal research came both from the universities, who see royalties as a potentially fruitful source of additional income, and from the Carter Administration, which had made patent law reform a major recommendation in last

year's domestic policy review of industrial innovation.

Under the terms of the new law, all federal research agreements with small businesses and non-profit institutions will carry a clause stating that the institution carrying out the research will own the 17-year rights to any patents provided certain conditions are met.

In the case of universities, all licensing agreements must be approved by the funding agency; exclusive licences can only be awarded to large companies for between 5 and 8 years, after which they must be made generally available; royalties must be shared with the inventor; and the balance of royalties or other income made after the deduction of reasonable expenses must be used to support scientific research or education.

In addition, the federal government retains "march-in" rights to direct the university to award licences if it feels these are being inadequately handled. Any products or processes arising from the patent for the domestic market must be produced "substantially" in the United States. The earlier requirement that universities should share their profits with the government has, however, been dropped.

The bill also included a separate section extending the copyright laws to cover computer software. At present, software compilers have no way of protecting their programs from being copied and used without their permission. Now a software program which has been copied can be used only where permission has been granted, or for archival purposes. **David Dickson**

## Stanford and UCLA plasmid patent

Washington

A patent was awarded last week covering some of the fundamental techniques used in recombinant DNA research and developed by Dr Herbert Boyer of the University of California, San Francisco, and Dr Stanley Cohen of Stanford University.

The patent covers a process developed in the early 1970s for inserting foreign genetic material into a bacterial plasmid. The method has since become widely used by almost all of the companies engaged in recombinant DNA research. These companies will now have to obtain a licence to use the techniques.

The patent, covering the United States only, was issued to Dr Boyer and Dr Cohen as inventors, but they have already agreed to assign the rights and royalties that may ensue to their respective institutions. Mr Niels Reimers, director of Stanford's technology licensing office, said, however, that any royalties demanded would be

"reasonable", and stressed that, at least initially, it was not expected to make a large amount of money from the patent. Also the techniques developed by Boyer and Cohen can still be used freely by scientists for research purposes.

The question of payment is sensitive. If the patent turns out to be lucrative for the two universities, it could be challenged on the grounds that the patent application did not acknowledge the contribution which scientists other than the two named inventors had made to the techniques described (*Nature*, 3 April 1980).

Several scientists said last week that they were waiting to read the details of the patent — and to see what licence fee Stanford and the University of California, San Francisco were likely to demand from private companies — before deciding whether to take any further action.

The terms of the patent, No.4237224, are intentionally broad. They cover "a method for replicating a biologically

functional DNA", and describe the various steps used to cleave viral or circular plasmid DNA, insert a separate DNA fragment, and grow up and separate unicellular organisms containing the altered DNA.

Still awaited is a decision from the Patent and Trademark Office on a second application made by the two universities on behalf of Dr Cohen and Dr Boyer, which covers any organism produced with the techniques covered in the first patent.

Mr Reimers said last week that, from the universities' point of view, this was likely to be the more important patent, since without its protection companies could manufacture products abroad using the recombinant DNA techniques, and subsequently sell them in the United States without having to pay royalties.

The Patent Office's decision on the second application is expected within a year. All such patent applications covering microorganisms had previously been held up pending a ruling from the Supreme Court, which decided in the summer that there is nothing in existing patent law which denies microorganisms protection.

Meanwhile, the University of California has filed a suit against the pharmaceutical company Hoffman LaRoche and the San Francisco firm Genentech, claiming that the two companies must pay damages to the university for the use of a cell line produced by university scientists which the companies have been developing as a potential commercial source of interferon.

The scientists at the University of California, Los Angeles who produced the cell line claim that it was passed to Hoffman LaRoche without their permission. But in the counter-claim Hoffman LaRoche is arguing that there were no conditions attached to the cell line when it was obtained indirectly through a researcher at the National Cancer Institute, and that the company therefore has no obligation to the university.

David Dickson

## Genetic engineering

### Hormone growth

Genentech, the California-based biotechnology company, will begin clinical trials of its latest genetically-engineered product, human growth hormone (HGH), in London this January. But Genentech's industrial partners in the venture, Kabi Vitrum AG of Sweden, are somewhat ambivalent about the development.

Kabi Vitrum is the major world producer of HGH, made at present from cadaver pituitaries. The hormone is used to treat HGH-deficient children, reckoned to be some 7-10 per million of population. But the nature of the source naturally limits production, and Kabi estimates the true market to be three times the present supply; so the firm searched for other sources. Genetic engineering was an obvious possibility, as HGH is a small

peptide, about the size of insulin.

So in 1978 Kabi asked Genentech to produce a strain of *Escherichia coli* containing the HGH gene. Under the contract, Kabi would have sole world production rights, except in the United States and Canada, where they would be shared with Genentech. But Genentech was successful sooner than Kabi expected, and further surprised the firm by making rapid preparations for commercial production. Genentech had been expected to stick to research.

Now Genentech is well ahead with pilot tests in 700-litre fermenters, while Kabi has been restricted to 10 litres by Swedish limits on scale-up of genetic engineering experiments; and Genentech plans clinical trials at Great Ormond Street Hospital for Sick Children starting in January 1981. Kabi, meanwhile, would wish to be more cautious. "We do not know about Genentech's toxicological testing" said Dr Bengt Karlsson, Kabi's managing director, "but we would not wish to put the product on clinical trial for at least six months". Nor is Kabi's caution due to lack of material, for they have access to Genentech's supply.

However, in London, where Dr James Tanner at Great Ormond Street will conduct the trial, it is felt that Genentech's toxicity testing has been quite sufficient. There have been plenty of animal and monkey tests, says Dr Tanner, and the UK Department of Health has passed the material for clinical trials. The Genentech HGH will be given to 20 patients for a year, 10 of them first treatments, and the other 10 already three years into a course of pituitary HGH. The main contaminant will be 1-2 per cent of bacterial protein; and the danger is that HGH-like proteins in this material may induce antibody formation to true HGH.

Dr Tanner welcomes the new source of the hormone. In the United Kingdom there are 100 new cases a year of HGH deficiency, and just enough pituitary HGH to go round (produced from 60,000 cadavers a year). But it is always "touch and go" each year whether sufficient cadavers will be made available. Moreover, if there were more HGH around, it could be tried out on more marginal cases of delayed growth, or slow bone healing after fractures.

Ultimately, Genentech will not be the source of HGH in Britain. Kabi announced last week that it has concluded a deal with the Department of Health for the Centre for Applied Microbiological Research at Porton Down to conduct scale-up trials on the Genentech bacterium. In exchange, Kabi will offer the product at a preferential price to the Department of Health, and assist Porton with its present production of HGH from pituitaries. (Kabi believes it has a more efficient extraction system.)

The centre is seeking permission from the Genetic Manipulation Advisory Group to ferment the engineered *E. coli* in

400-litre vats; and to satisfy GMAG, it must show that the organism is killed in the closed fermenter before the material is extracted.

Despite early misgivings, the Department of Health has begun to encourage Porton to become involved with industrial applications of the recombinant DNA technique — Unfortunately nothing has yet come forward in the United Kingdom that fits the bill. Dr Peter Sutton, director of Porton, is delighted at the deal with Kabi: "It means we can get our feet wet" with commercial scale genetic engineering, he said last week.

Robert Walgate

## US Administration

### Reagan's men?

Washington

President-elect Ronald Reagan's transition staff is sifting through the list of candidates for top-level positions in the new Administration, and the names of the first cabinet appointments should be announced this week. Potential choices have been widely discussed in the press — often names intentionally leaked to gauge public reaction — so few major surprises are expected.

Top candidate for the renamed Department of Health and Human Services (DHHS), responsible for the biomedical research budget of the National Institutes of Health (NIH), is Senator Richard Schweiker, Mr Reagan's running mate in his bid for the 1976 Republican nomination.

Mr Schweiker gave up his Senate seat earlier this year to work for Mr Reagan's election. In the Senate he was an active member of the Labor Committee's health and scientific research subcommittee, and as ranking minority member often supported the initiatives of the committee's present chairman, Senator Edward Kennedy.

Mr Schweiker is "definitely pro-science", one NIH official said last week, although adding that he had received some criticism for inserting in the institutes' funding legislation a clause that requires special arrangements for supporting research in diabetes and digestive diseases — the type of constraint that NIH prefers to work without.

The appointment would be less popular with labour unions, since Mr Schweiker is the sponsor of a bill designed to restrict the activities of the Occupational Safety and Health Administration.

As DHHS Secretary, Mr Schweiker would be responsible for the budget and activities of the National Institute of Occupational Safety and Health, part of the Center for Disease Control.

A predecessor in that post, Mr Caspar Weinberger, is widely tipped as next Secretary of Defense. He was director of the Office of Management and Budget under President Nixon, where his financial

stringency earned him the nickname "Cap the Knife". He was later promoted to Secretary of the then-named Department of Health, Education and Welfare at a period when biomedical research was becoming dominated by a congressional "disease of the month" approach.

Various names are being discussed for the position of Under-Secretary of Defense for Research and Technology, responsible for the Pentagon's massive research budget. They include Mr William van Cleave, at present head of Mr Reagan's defence transition team, and Mr Benjamin T. Plymale of the Boeing Corporation, who was the source of controversy last year when his security clearance was temporarily revoked.

No clear candidate has yet emerged to head the Department of Energy. One suggestion, Mr Michel Halbouty, a Houston oilman and geologist who was Reagan's chief energy strategist during the campaign, is being opposed by some influential Republicans because of his lack of government experience. Others have opposed the nomination of Mr Frank Zarb, a top energy official in the Nixon and Ford administrations, because of his involvement in setting up the present system of price controls on crude oil and gasoline. Two possible contenders are Dr John Sununu, professor of engineering at Tufts University, Massachusetts; and Representative Clarence Brown of Ohio.

Appointments at a lower level, including the heads of independent agencies such as the National Aeronautics and Space Administration, are not likely to be announced until the main cabinet posts have been filled.

In the science field, these appointments will also depend on the report of the science and technology transition team under Dr Simon Ramo of TRW and Dr Art Bueche of General Electric.

Dr William A. Nierenberg, director of the Scripps Institute of Oceanography, is widely mentioned as possible director of the Office of Science and Technology Policy (OSTP), as is Dr Guyford Stever, ex-director of the National Science Foundation, who held the OSTP job for a few months at the end of the Ford administration.

At the National Science Foundation (NSF) itself, the Reagan administration seems unlikely to overturn the appointment of Dr John Slaughter as director. Dr Slaughter was sworn in two weeks ago, and that the emphasis that he is keen to put on the development of engineering and applied research should match Republican goals for science.

Finally, the appointment of Dr Frank Press, the present director of OSTP and President Carter's Science Advisor, was assured as the next president of the National Academy of Sciences when nominations for the post closed last Monday without any other names having been put forward.

David Dickson

## Soviet plans

### Science on tap

Soviet science is to be geared even more closely to the needs of the economy, according to the guidelines for the 11th Five Year Plan, published last week. The plan calls for a substantial reduction in the time taken to disseminate research results, strengthening of the links between research and production, better coordination between scientific establishments and an improved basis for scientific planning.

Individual research priorities specified by the guidelines range from the immediately practical (the improvement of computer technology and software) to the long-term (creation of the bases for thermonuclear power engineering), and from the further conquest of space to greater environmental protection and economic utilization of the biosphere. Biotechnology to produce new compounds with tailor-made properties, particle physics and immunology all receive special mention.

At this stage of planning, however, no specific targets are mentioned, nor is the financing of science discussed. The emphasis on closer links between science and industry, however, and the statement that ministries and departments are to bear increased responsibility for industrial research may have some financial implications. Their responsibility will presumably also include the planning of research in institutes under their control. One of the main complaints of Soviet scientists in recent years has been the inflexibility of research plans once approved. The new guidelines, however, urge that the direction of research and development should be "determined in good time . . . and changed to meet the demands of the scientific-technological revolution".

All this, however, depends on an overall increase of labour productivity. In industry, this increase is specified as 23–25 per cent, which is to account for more than 90 per cent of the increase in output. For the scientists no such target is set, perhaps because the recent "press debate" in *Literaturnaya Gazeta* has revealed only too clearly how much scientists resent having their intellectual performance monitored.

## DNA guidelines

### Bowing out

The US National Institutes of Health (NIH) are facing a virtual revolt from local Institutional Biosafety Committees (IBCs) over whether there is still a need for strict surveillance of research using recombinant DNA techniques.

At a meeting in Washington organized by the National Institute of Allergy and Infectious Diseases, the predominant view

of the chairpersons and representatives from more than 150 IBCs throughout the country was that the prime role of the IBCs has become largely a public relations exercise.

Few of those attending the meeting were prepared to accept that recombinant DNA research presented any greater health or environmental hazard than work with unaltered organisms not covered by the NIH guidelines.

Many complained of the amount of paperwork they are required to carry out, particularly in the light of recent revisions of the guidelines, which have shifted most of the responsibility for reviewing research protocols from the NIH's Office of Recombinant DNA Activities to the local level.

The Washington meeting had originally been called for IBC chairpersons to discuss how their committees were operating. But the main focus of the two-day meeting rapidly became whether the IBCs — or even specific regulations covering recombinant DNA research — were any longer needed in their present form.

According to one NIH official, the mood of the meeting was that the amount of time that IBCs put into DNA issues was out of proportion to all sorts of other bio-hazards.

One recommendation being forwarded to next month's meeting of the NIH's Recombinant DNA Advisory Committee is that all experiments using the disabled K12 strain of the bacterium *Escherichia coli*, or the yeast *Saccharomyces cerevisiae*, as host-vector systems should be totally exempt from the guidelines.

In the case of *E. coli*, the same suggestion was made last year, but the advisory committee then recommended — and NIH director Dr Donald Fredrickson agreed — that although prior approval was no longer necessary for such experiments, the requirement that the experiments be carried out under P1 physical containment conditions should remain.

Members of biosafety committees also complained about the additional paperwork resulting from NIH's requirement that, although details of all approved experiments no longer have to be registered, they must keep detailed records of all recombinant DNA work carried out in their institutions.

The latter requirement was partly the result of a survey at Stanford University in California which showed a discrepancy between the rate at which different committees required experiments to be reclassified, possibly indicating that some were interpreting the guidelines more strictly than others.

But the IBC members balked at yet more paperwork.

A straw vote taken during the final plenary session of the meeting revealed little support for the proposal that NIH should keep a record of all recombinant DNA research carried out under the guide-

lines, a small majority for recording research carried out under P2 containment conditions and above, and a larger majority for keeping a record merely of all research in P3 and P4 containment conditions, the two strictest categories.

Reflecting their general belief that recombinant DNA research no longer represents a greater hazard than ordinary research with microorganisms, many committee members were sceptical about the value of a broad study of the effectiveness of IBCs which NIH is now preparing.

If the committees had any value, it was felt, it had been in calming public fears about the health implications of such research. Mr Ray Thornton, for example, recently appointed chairman of the advisory committee, said that the careful supervision of experiments had been largely responsible for the general development of public confidence.

Other speakers suggested that, even if no extra hazards had been identified, the public discussion raised by initial fears had helped to generate a consciousness about the need to watch for biohazards in general.

## Yugoslavia now

### Supek's worry

Yugoslavia could shortly face economic collapse if the planners fail to make proper use of the country's scientific personnel. This is the opinion of Dr Ivan Supek, the Yugoslav physicist and philosopher, in London this week for a Pugwash meeting.

Yugoslav scientific and academic life, says Dr Supek, has almost completely lost the impetus of 20 years ago. The financing of basic research is hampered by a bureaucratic system which allegedly subordinates research to consumer control. But reliance on foreign licences (usually purchased when already obsolescent) means that the technological base required by Yugoslav industry and agriculture is either inappropriate or altogether absent.

The chief factor in the decline, according to Dr Supek, is excessive party and state control over science. After the hardliners' coup of 1971, the universities lost much of their autonomy, including the right to elect their own deputies to parliament. (Dr Dupek himself was a non-party deputy from 1963 to 1967.)

At the same time, the university structure was decentralized. The University of Croatia, for example, was divided into four separate universities (Zagreb, Split, Rijeka and Osijek) and the individual faculties, rather than the university as a whole, became the basis of planning and financing. Frequently, said Dr Supek, decision-making fell into the hands of party members with no particular academic background.

Under these arrangements, "censorship by budget" was made easier. Among the

victims of this process was the *Encyclopedia Moderna*, a philosophy of science journal edited by Dr Supek himself.

Dr Supek stresses that it is not the "self-management" process — Yugoslavia's special contribution to socialism — which is at fault. If the current trend towards bureaucratic centralism could be reversed, he said, and "self-management" restored to scientists, both basic and applied research would benefit. At present, however, self-management is simply a slogan.

Such official duplicity, said Dr Supek, is nothing new in Yugoslav science. In 1956, when Yugoslavia began a nuclear research programme, Dr Supek, as director of the prestigious Rudjer Boskovic Physics Research Institute, found himself *ex officio* on the country's atomic energy commission. Although the programme had, officially, a purely scientific and peaceful orientation, its members included the Minister of Defence Ivan Gosrjak and

Supek (right) and defence minister, 1956

Minister of Internal Affairs Alexander Rankovic. Their presence made Dr Supek extremely sceptical of the true aim of the programme, and made him a fervent opponent not only of nuclear weapons but of all applications of nuclear energy.

The duplicity, which, in Dr Supek's words, is allowing self-management to be killed in the name of self-management, will be a major obstacle to any move by the scientists to regain their pre-1971 position. The recent ban of the proposed cultural and sociological journal *Javnost* was justified by the Belgrade authorities on the grounds that the journal was meant to be a front for a would-be cultural elite. Dr Supek, however, is strongly opposed to elitism, and would claim for science only that right of self-government which is constitutionally guaranteed to all Yugoslav workers. The Party hardliners, however, are not prepared to yield without a struggle. Recently agronomists working on the forthcoming five year plan proposed that, for modern farming methods to be introduced, the maximum peasant holding should be increased from 10 to 50 hectares. But in spite of the deteriorating state of Yugoslav agriculture, the proposal was rejected as liable to cause class conflict.

Vera Rich

## Agricultural research

### Ministry at top

An impending change in the relationship between the Agricultural Research Council and the Ministry of Agriculture, Fisheries and Food (MAFF) now seems likely. Most probably, the council will in future be more directly subject to the ministry. In this respect, it is likely to be worse off than the Medical Research Council, which in October reached an arrangement with its chief sponsoring department of government, the Department of Health and Social Security, that some £12 million of "Rothschild money" should be transferred back to its own annual budget.

Change has been in the air since the publication of a report of the Public Accounts Committee in July 1979 which suggested that the government should consider transferring a further slice of the ARC budget to the agriculture ministry. The underlying principle is that put forward in 1971 by Lord Rothschild, who advocated giving control of research budgets to the chief users of the results of research — the ministerial "customers". At present, some 40 per cent of the research council's spending derives from the ministry, and the Public Accounts Committee was asking why the balance should not be shifted further.

For the past year, a committee under the chairmanship of Sir Brian Hayes, permanent secretary at the ministry, has been trying to decide what should be done. The alternative to a further transfer of funds is a more direct influence by the ministry on the policy of the council. Although a decision has not yet been reached, the second course is the more likely. Either way, the council is unlikely to be overjoyed.

Like many government-supported institutions, the council (ARC) has been hard-pressed to operate within its cash limits during the financial year 1979-80. Nevertheless, by the end of that year, says its annual report published last week, it had managed to plan a reasonable research programme for 1980 and beyond by concentrating its efforts on high priority research.

The council's choice of priorities was effectively made by MAFF which has cut the amount of research it is prepared to buy in some of the ARC's research institutes while increasing it in others. MAFF currently pays for about half of the work conducted in ARC institutes under the Rothschild customer-contractor principle.

MAFF is particularly keen to encourage food research, interest which has proved lucky for the ARC's Meat Research Institute whose grant of £370,000 from the Meat and Livestock Commission was cut last September. MAFF has stepped in to make up some of the loss. It has also increased its contribution to the budget of the Food Research Institute in Norwich.

the extra support going mainly to research on biopolymers, nutrition and biotechnology. This new emphasis coincides with a reorganization of the Food Research Institute and the setting up of a joint ARC-Medical Research Council working party on food research policy.

Irrespective of MAFF, ARC has been increasing support for research in priority areas, in particular by introducing a new scheme for supporting work in universities outside the normal research grant system. ARC research groups in photosynthesis have been set up at the universities of Leeds and Sheffield and at Imperial College, London; and at the University of Bristol a group has been established in the neurobiology of animal behaviour and reproduction. The ARC's plans for the forthcoming year include the establishment with the Medical Research Council of a new unit at Edinburgh on neuropathogenesis.

## British dentists

### Broader, better

The proposal that dentists newly qualified from British dental schools should not be allowed to practise without first spending a year in supervised practice is the chief recommendation of an inquiry into dental education, commissioned by the Nuffield Foundation and published earlier this week. The inquiry was directed by Sir Gordon Wolstenholme and supervised by a steering committee under Professor T. C. Thomas, previously vice-chancellor of the University of Liverpool.

British dentistry, long saddled with an international reputation not very different from that of the British motor car industry, is offered a cheerful future in the report (to be had from the Nuffield Foundation at £4.50). The incidence of caries among children is decreasing, dramatically so in cities such as Birmingham where there has been fluoridation of water supplies for some time. In the ten years from 1968, the proportion of the British population entirely without teeth (described in the report as "the edentulous state") decreased from 36 per cent to 29 per cent.

Part of the stimulus for the inquiry was the recognition that dentists now being trained would still be in practice when the state of British dental health has been further transformed, so that the pattern of practice will have changed, and when novel dental technology will be available.

The theme of the inquiry's report is that dentists should be trained for flexibility. The dental schools are told that their present output of professionals is likely to be sufficient for the future, but that British dentists should rely more than is their present habit on ancillaries, especially hygienists and therapists, all of whom are in need of more explicit training and career structures.

On the curriculum of the dental schools,

the report argues for greater attention to basic science and the early introduction of students to clinical work. Present dental courses are too narrowly vocational, and should be broadened but not lengthened (at present training lasts four or five years). Instead, the argument goes, there should be a pre-registration year.

But where? Newly qualified physicians spend their pre-registration years in hospitals, but dentists have no comparable places of supervised work. The committee suggests a system of supervision in practice organized by the dental schools and based on the Community Dental Service or on the dental services provided for the forces. It also wants to see a period of vocational training in the first two years of a dentist's regular practice and more opportunities for in-service training than there are at present.

The committee of inquiry also asks that steps should be taken to increase the present scale of dental research in Britain, including the setting up of a national research centre. One obvious present difficulty is that most dental research is at present undertaken on short-term research grants.

The committee neatly skirts around the most contentious problems in British dentistry — how should dentists be paid? It echoes the general discontent (shared by some dentists and most National Health Service patients) that the present system of piecemeal payments is unsatisfactory, but judiciously recommends that professional organizations "should seek a system of payment . . . other than that existing at present".

## Israeli science

### Crisis at Weizmann

Financial crisis threatens the "very existence" of the Weizmann Institute of Science, Israel's private and principal research institution — or at least that is what Weizmann president, Professor Michael Sela, told the governing body recently. But according to the Weizmann Institute Foundation in London, which helps to raise money in the United Kingdom for the institute in Israel, the Weizmann finances have never been better.

Somewhere between these two statements lies the true position — that the Israeli government, which provides 45 per cent of the institute's running costs, has announced government spending cuts which will reduce its contribution to the Weizmann Institute by 7½ per cent (in real terms) compared with last year; and that Professor Sela was painting a grim picture to drum up support from the Weizmann's foreign friends, who are strongly represented on the governing body.

Foreign endowments and bequests from Europe as well as the United States contribute around 20 per cent of the Weizmann's funds. While these contri-

butions have been increasing, they have not kept up with inflation outside Israel — except for the United Kingdom, whose donation has increased by two-thirds in the past two years. This is due to the encouragement of Lord Sieff, chairman of the major British chain store Marks and Spencer, and also chairman of the Weizmann Institute board of governors.

The net result is that the Weizmann budget will be static this year (October 1980 to September 1981) in dollar terms at about \$30 million, whereas institute officials would have liked to see a small growth to take into account inflation abroad (where scientific equipment, for example, must mostly be bought).

Nevertheless, in 1980 funds were sufficient to establish, on a scientific staff of 300, five new "career development

Sela, crying wolf??

chairs", as an exercise to introduce new talent to the campus, and 10 professorial chairs. Money for these came mostly from the United States, but also from France and South Africa. Two new research centres were also established within the institute: the K. B. Weissman Institute of Physical Sciences and the Melvyn A. Dobrin Centre of Plant Research. Moreover, the Yeda Research and Development Company, which acts as a link between the institute and industry, increased its turnover to \$4.5 million in 1980, compared with \$1 million three years ago. (One recent venture, Inter-Yeda, manufactures human fibroblast interferon for use in clinical trials.) The government cuts must therefore be seen in the context of a recent very healthy spending pattern at the Weizmann.

Nevertheless, 70 per cent of the institute's budget is spent on salaries; so the effect of a cut in total budget is magnified when compared with the 30 per cent the institute has to spend on books, equipment and fuel. Bequests on the whole do not provide these items; so cuts are, in the end, having to be made in these financially marginal but scientifically significant areas. Because a potential donor is not likely to want his name on a batch of test tubes or even a spectrophotometer, the Weizmann may find it more difficult to raise this kind of small change abroad.

Robert Walgate

## CORRESPONDENCE

## Medical schools

SIR — Although your editorial of 27th November 1980 on the reorganization of London Medical Schools has some hard things to say about London University in general and some of its senior members in particular, for these your writer may perhaps be forgiven, since they are largely matters of opinion. Less forgivable, however, are the errors of fact that spice the article. I wish to draw attention to only two of these. You refer to "two preclinical schools (at King's College and Westminster Hospital)". The Westminster Medical School has no preclinical departments of its own: King's College is a preclinical school for both King's College Hospital Medical School and the Westminster Medical School. More important, you continue "... the effect of the Senate's decision is that the preclinical schools at King's College and Westminster Hospital (sic) should be closed ...". The Senate's decision implies nothing of the sort: all preclinical schools of the University, including that at King's College, are to be reinvestigated in the next few months. Which school, if any, is to be recommended for closure is still a matter of speculation, even for members of the new Working Party. The article does contain one germ of good sense, where it refers to planning. If there is or ever has been a plan, would that the hewers of wood and drawers of water could be told it.

## Badgers and TB

SIR — Following public criticism of the policy of the Ministry of Agriculture, Fisheries and Food (MAFF) for dealing with badgers infected with tuberculosis (TB) the Minister of Agriculture asked Lord Zuckerman to take an objective look at the relationship between badgers, cattle and bovine TB, and to advise on how the problem should be tackled in the future. This is a complex question. The Mammal Society agrees with Lord Zuckerman's basic conclusion that the badger is a major reservoir of bovine TB in certain limited areas of South West England, and hence is a potential danger to the cattle in those areas. However, we feel that the report gives a biased interpretation of the evidence, and that many of Lord Zuckerman's conclusions were not justified from the data presented in the report. We would like to correct some of the factually misleading statements.

During the period of the moratorium on gassing, the percentage incidence of TB in badgers from Gloucestershire and Avon increased, an observation that Lord Zuckerman took to imply that the disease has "spread". The fact that the percentage incidence declined slightly in Cornwall during the same period was overlooked (p. 63). Also, Lord Zuckerman's statement (p. 40) that at

least one in five to one in ten badgers in affected areas is now infected with TB is misleading. The incidence quoted relates largely to samples taken in the vicinity of TB outbreaks in cattle, and there is no reason to believe that such high levels of TB are to be found except in very small pockets of infection. Certainly there is no scientific evidence to justify Lord Zuckerman describing badgers in the South West as a "highly-infected population" spreading TB to badgers in other areas.

Since TB in badgers appears to be confined largely to limited areas of the South West, and since the evidence to suggest that the disease is spreading is equivocal, we strongly contest Lord Zuckerman's view that bovine TB is a major hazard to the survival of the badger.

Lord Zuckerman stated (p. 27) that the gassing of badgers was accompanied by a decline in the number of reactors in the cattle herds concerned, and that the two events were related. However, the rate of decline in the incidence of TB in badgers in the South West was paralleled by a decline in the incidence of reactors in cattle herds not only in the South West but also in the rest of England. The timing and rate of decline were similar in all three samples. Lord Zuckerman offered no explanation for this. One possible interpretation is that the incidence of TB in both badgers and cattle underwent a decline throughout the country, and that the badger gassing campaign had little significant effect on the overall timing or rate of decline, though gassing may have affected the situation locally.

Lord Zuckerman concluded that the appearance of the disease in cattle in the South West reflected a high local prevalence of TB in badgers (p. 41). This is manifestly untrue; in Cornwall only 15 per cent (51/340) of herd infections were definitely attributable to badgers (p. 57).

Lord Zuckerman stated that "population density is a major factor in the spread of TB". Certainly it is probable that population density is a factor in the spread of disease, but other more subtle factors may be significant. Badger and cattle densities<sup>2</sup> in parts of Dorset and Somerset are as high or higher than in Gloucestershire, Avon and Wiltshire, yet the incidence of TB is very much lower. Why? Also, the presence of infected badgers does not always result in reactors in nearby cattle herds (p. 21). Why?

Lord Zuckerman speculated that badgers all over the country once suffered and died from TB, and that the prevalence of TB in badgers had declined in parallel with the decrease in the incidence of TB in humans and cattle (p. 41). But since badgers are a self-perpetuating reservoir of tuberculosis (p. 95), it is difficult to see why, when the incidence of TB was reduced in cattle, it should also have declined in the badger. This is particularly inexplicable in areas such as parts of South East England and North Wales, where badger densities are comparable to those in the South West (p. 68). In the absence of any evidence to support Lord Zuckerman's view, it seems more logical to speculate that TB was never as prevalent in badgers in the rest of England. So what factors make the situation so different in parts of the South West?

There are many anomalies in the data presented in the report; we have only mentioned a few. Clearly many issues remain unresolved, and there are likely to be many subtle factors involved in the process of transmission of TB from badgers to cattle which are not yet understood. We believe that the continuation of the badger gassing campaign should only be regarded as a short-term expedient. Lord Zuckerman accepted that eradication of TB in badgers is probably impossible (p. 27). In that case, there is every reason to suppose that if/once gassing operations cease, and the badger population builds up again, the incidence of TB in the badger will also increase. In order to achieve an acceptable long-term solution we believe that it is imperative that further research is undertaken to (1) explain some of the many anomalies in the data available and (2) understand the factors involved in the transmission of TB from badgers to cattle.

## Court feasibility

SIR — Your United States election scoreboard of plusses and minuses (*Nature* 13 November, p. 107) scores the President-elect's statement that he would explore the feasibility of a "science court" as a "plus". This seems only justifiable if one regards a statement that feasibility will be explored as preferable to one that the concept will be implemented. At the risk of making a hackneyed point that is, however, evidently unfamiliar to your reporter, it cannot be too strongly emphasized that the procedures of science and a court of law are necessarily different. To take only the best known example: the verdict of a court of law can take only one of two values — guilty or not guilty. In science, there are no probabilities that are equal to zero or one.

Ciba-Geigy AG,  
Basle, Switzerland

## Plusses and losses

In the article by David Dickson on the likely consequences of the election of Mr Ronald Regan as President of the United States, published on 13 November, the likely changes in US science policy were described as "Plusses" and "Minuses", not as "Winners" and "Losers" as in the original article. The complaints of Messrs Noble, Klimowsky, Volliamy, Price and Joyce (*Nature* 27 November) therefore lie against the London office and not against Mr Dickson.

EDITOR, *Nature*

## NEWS AND VIEWS

# Conflict and commitment in neural development

from Miranda Robertson

Two controversial questions dominate research on the development of the nervous system. The first, which has the longer history of controversy, is that of how growing nerve fibres make specific connections with their targets. The second is that of the extent to which neurotransmitter specificity is induced by the micro-environment of the nerve cell or its axon during development. It was clear from the collision of views at the annual Symposium of the British Society for Developmental Biology\* that both issues remain contentious, but for different reasons.

## Specification of connections

The principal difficulty with research on the specificity of connections (or Sperry-ficity, as one participant nicknamed it) is that the complex results of manipulating an embryo have too often been interpreted on the basis of too limited an investigation. One of Sperry's own first contributions to the field was to reinvestigate in detail the effects on the motor performance of adult animals of crossing their motor nerves, which was said at the time to lead to central respecification and the reestablishment of normal movement. Sperry showed that no such respecification occurred and the 'normal' movements resulted from a good, but imperfect adaptation on the part of the animal to the handicap. It is therefore somewhat ironic that one of the more recent contretemps in the field, which also concerns the respecification of connections, though in embryos, not adults, has in its turn recently been resolved by close attention to anatomy. The argument, recapitulated by J. Feldman (London), was over Jacobson's elegant experiments apparently showing respecification of the dorso-ventral and antero-posterior polarity of frogs' eyes after very early rotation of the eye cup<sup>1</sup>. Feldman and others working in M. Gaze's laboratory consistently failed to replicate Jacobson's electrophysiological evidence for normal retinotectal maps in the adult animals, and the conflict was resolved only when an examination of the eye itself revealed that rotated eyes are usually replaced gradually by new eyes which regenerate from residual unrotated tissue<sup>2,3</sup>. Gaze and his colleagues examined their animals early, before

regeneration was complete; Jacobson examined his later: hence the conflicting results. In fact, the balance of the evidence now suggests that the polarity of neural tissue is irreversibly determined very early in development and rotation of embryonic tissue is one of the few manipulations that does not result in respecification: instead, the nerves tend to re-rotate *en route* to their targets.

The focus of controversy has now switched to the question of how far general properties such as polarity can account for the precision of individual connections between one array of nerve cells and another. There are two extreme positions on this. One is that given a fixed polarity and a chemical signal that determines the general direction of growth, the orderliness of connections can be ensured simply by the strict preservation of neighbour relations, possibly by general adhesiveness between growing fibres. The other is that nerve fibres are guided to their destinations by specific chemoaffinity between an individual innervating neurone and its target. Neither of these mechanisms however can account for the flexibility shown by growing nerve fibres in response not only to experimental manipulation but to the demands of normal growth.

For example, both the retina and the visual tectum of the frog *Xenopus* grow continuously throughout life. But the retina grows concentrically, whereas the tectum grows from rostral-lateral to caudomedial; so in order to maintain an orderly map, connections between the two must be continuously broken and re-established (M. Keating, NIMR London). This rules out strict chemoaffinity and implies that incoming nerve fibres are ordered relatively rather than absolutely. That the ordering is relative with respect to the other nerve fibres as well as to the target follows from the results of removing either half of the retina, or half of the tectum in developing fish, amphibia or hamsters<sup>4</sup>. When the optic nerve fibres arrive at the tectum, they spread out over the whole tectum, or squeeze up into half of it, respectively, in an orderly fashion.

On the other hand, there is evidence against the preservation of neighbour relations by general adhesiveness. The ordering of nerve fibres is not always reflected in their physical relationships to one another: in both *Xenopus* and cat,

nerve fibres leave the retina in an orderly manner, become increasingly disordered on the way to the tectum (or in the case of the cat, the lateral geniculate), and re-establish order once more just before arrival<sup>5,6</sup>. It is thus more as though fibres are assigned intrinsic positional values which govern their actual positions only in response to local cues, for example at the target. Furthermore, it is clear that the response may not result in the simple establishment of linear order. For example, in the optic chiasm of mammals, half the fibres of each eye follow a course to the contralateral side of the brain while the other half turn to make connections on the ipsilateral side. Similarly, even in the ribbon nerve of the cichlid fish, in which neighbour relations are rigidly maintained over most of the pathway, the fibres undergo systematic piecemeal rearrangement at the point of their entry to the tectum (J. Scholes, Kings College London)<sup>7</sup>.

The one system in which neighbour relations do seem to be rigidly maintained throughout is the retino-tectal map of the chick. Not only does the retino-tectal projection remain orderly throughout its course, but, unlike those of hamsters and frogs, it fails to compensate for ablation: removal of part of the developing retina results in a corresponding area of denervated tectum (W.M. Cowan, Salk Institute)<sup>8</sup>. This inflexible behaviour on the part of the chick optic nerve has been the main support for the school of thought favouring a simple neighbour-relations mechanism for the specification of connections. The alternative point of view is that the chick retino-tectal projection is a less plastic manifestation of the same mechanisms that operate in fish, frogs and mammals.

This point of view is certainly easier to reconcile with other aspects of neural development in the chick itself. Nearest-neighbour guidance is plainly inadequate to explain the pattern of connections between spinal motor neurones and the muscles of the chick limb, which have been investigated in considerable detail in the laboratory of L. Landmesser (Yale University).

Like the eye, the spinal cord seems to

Miranda Robertson is associate editor of Nature.

\*The Symposium of the British Society for Developmental Biology on Development in the Nervous System was held in Southampton on September 9-11 1980.

acquire an irreversible polarity very early in embryogenesis. If small sections of chick spinal cord are reversed before the outgrowth of motor nerve fibres, the axons will correct for the reversal and adjust their paths so as to connect with the muscles appropriate to their original position<sup>9</sup>. This is at first sight inconsistent with the results of Stirling and Summerbell<sup>10</sup>, who reversed the limb bud instead of the spinal cord and found that ingrowing motor neurones failed to correct for the reversal. Landmesser and her colleagues have suggested two ways in which this failure could be explained without abandoning the principle of early determination of polarity. The first is to postulate that because there is no conflict between the polarity of the nerve fibres and that of their environment until they actually enter the limb, nerve fibres growing into a reversed limb bud are simply not alerted to the reversal until it is too late for them to change their paths. Landmesser finds that nerve fibres from reversed segments of cord begin to adjust their courses soon after they have left the spinal cord, which suggests that the fibres are guided at least partly by morphogenetic signals that operate before they enter the limb. The second explanation for the conflict between Landmesser and Stirling is that there are limits to the extent of the reversal a nerve fibre can correct. Landmesser finds that after cord reversal limited to 2 or 3 segments, motor nerves can always correct their paths, whereas reversals involving 4–6 segments may defeat them. Her detailed investigations on the innervation pattern resulting from reversal of 4–6 lumbosacral segments suggest that the nerve plexus at the base of the limb may be crucial in sorting out the branching pattern of the ingrowing nerves, and that nerves that fail to enter the correct bundle at the plexus are usually the ones that innervate the wrong muscles. Even then, however, some nerves reach their own muscles by taking novel pathways in the limb.

These results plainly imply relatively specific local signals; but a recent ingenious attempt by Lewis to test for the presence of specific chemoaffinities in the chick wing raises the possibility of other interpretations. Lewis traced the fate of the brachialis longus inferior nerve in the wings of chicks in which one wing bud had been grafted onto the end of another before the outgrowth of motor axons<sup>11</sup>. In a normal wing, this nerve branches into three at the elbow, the median nerve proceeding to the wing tip. In the experimental wings, however, the median nerve on arriving at the wing tip is confronted with a second elbow. But instead of growing onto the second wing tip, as would be predicted on the basis of chemoaffinity, the nerve branches again exactly as the brachialis branched at the first elbow.

There are three ways of explaining this result. Perhaps the growing median nerve contains components of the other two

branches which would normally be eliminated once the nerve reached its target, but which given a second chance home to their own muscles. This could be tested by tracing their central connections. The second possibility is that purely mechanical factors determine the branching, and chemoaffinity operates only very close to the target. The third possibility is that the median nerve is behaving like the optic nerve of an amphibian half of whose retina has been removed, and spreading out according to its relative positional values to innervate the entire limb. More detailed investigations will be needed to resolve these ambiguities.

### Neurochemical differentiation

By contrast with the resistance shown by nerves to respecification after tissue rotation, developing neurones show a surprising degree of flexibility in the face of simple transfer up or down the antero-posterior axis. Most strikingly, Le Douarin and her colleagues (CNRS, Nogent-Sur-Marne) have shown that autonomic neurones from differentiated adrenergic ganglia of chick embryos can be induced by back-transplantation into an earlier host at a different position to express cholinergic functions, with appropriate changes in connectivity. One possibility that has excited a great deal of interest is that the switch in neurotransmitter specificity may be the consequence of the change in connectivity: that is, that it is induced by the target organ. An important source of support for this idea has been the work of Patterson and his colleagues on the neurochemical differentiation of rat sympathetic ganglion cell *in vitro*.

They have shown that in the absence of other tissues, the dissociated neurones develop adrenergic properties, but cholinergic differentiation can be induced by co-culture with certain non-neuronal tissues, such as heart, or by soluble factors released by them. The main argument against an induced switch in neurotransmitter synthesis rests on the alternative possibility that environmental factors, or target organs, are selectively enhancing the survival of cholinergic neurones from a heterogeneous population. (This argument will be discussed in greater detail in a later report of a CIBA symposium on the development of the autonomic nervous system.) While selective cell death is without doubt an important mechanism in neural development, it cannot in fact account for the phenomena described by the Harvard group, which have now been followed at the single-cell level *in vitro*. The real question is whether they play any part in normal embryonic development. Thus one of the most important advances reported at the Symposium was the morphological investigation of sweat glands in the rat foot pad, which show evidence of a change from adrenergic to cholinergic innervation between 7 and 14

days after birth (S. Landis, Harvard University). At the 7th postnatal day, the neural network surrounding the developing glands stains brightly with fluorescent markers for endogenous catecholamines; thereafter, catecholamine fluorescence wanes and acetylcholinesterase staining increases. These changes are paralleled by corresponding changes in the appearance of the vesicles in the nerve endings: predominantly small granular adrenergic vesicles give way to larger, clear cholinergic vesicles.

It is possible to quibble about these results: the interpretation of vesicle morphology is not easy, and in this case it is complicated by the fact that although the endogenous catecholamines disappear, a specific uptake system for exogenous ones remains. However the observations are at the very least consistent with a transition from adrenergic to cholinergic function during normal development *in vivo*, even if it has not been possible yet strictly to rule out the retraction of early adrenergic fibres and their replacement by new cholinergic ones.

### Differentiation of glia

If experiments *in vivo* are essential for establishing the relevance of phenomena *in vitro*, experiments *in vitro* are equally important for dissecting the bewilderingly complex interactions that take place *in vivo*. An important prerequisite for such dissection is a battery of specific markers for distinguishing between interacting cell types; and progress in the development of cell-type specific antibodies has recently been responsible for some interesting advances in the study of neurone-glia interactions. M. Raff and his colleagues (University College London) have been able to demonstrate that astrocytes, ciliated ependymal cells and oligodendrocytes differentiate in dissociated cell cultures of 10-day-old embryonic rat brain with exactly the same timing as they do *in vivo*, showing that the events that lead to their differentiation are already determined by 10 days' gestation and are not disturbed by the subsequent disruption of their positional relationship.

J. Brookes (California Institute of Technology), investigating later stages in the differentiation of peripheral glia, has established the existence of two inducible biosynthetic systems in Schwann cells. Contact with large axons (that is, axons which they would normally myelinate) induces an increase by at least 1,000 fold in the synthesis of the principal myelin protein P<sub>0</sub>. More surprisingly, purified Schwann cells can be induced by co-culture with primary muscle cells to synthesize acetylcholine. The observation that Schwann cells can synthesize acetylcholine is not new: after denervation of vertebrate muscle *in vivo*, they have been shown to migrate into the region of the endplate where they secrete acetylcholine<sup>12</sup>. The new contribution of Brookes's experiment is

# Cretaceous ammonites

from M. K. Howarth

AMMONITES are an extinct group of Cephalopods that flourished during the Mesozoic era 240 to 65 million years ago. Their world-wide distribution and speed of evolution, reflected in distinctive shell features, makes them the most useful macrofossils in the Mesozoic for relative dating of rocks. Rock divisions representing time intervals as small as about one-third of a million years can be recognized.

Ammonites from coastal exposures of Upper Cretaceous rocks in Zululand and Pondoland in South Africa are splendidly illustrated in a recent work by Klinger & Kennedy\*. Abundant representatives of

M.K. Howarth is in the Department of Palaeontology, British Museum (Natural History), London.

the subfamily Texanitinae were found in two areas 350 miles apart. Careful stratigraphical collecting showed that in each case there are complete series of transitions between the same four successive species, two of the ancestral *Texanites*, two of the successor *Submortonicerases*. Although the four species showed very high variability in both areas, there are small consistent differences between the same species in the two areas that are held to be of subspecific rank. It seems that the two populations were sufficiently isolated geographically to maintain these subspecific differences, but contact between them was enough to ensure that they evolved in parallel in specific and generic characters.

In the past ammonite systematics became unnecessarily complicated as generic and specific divisions were multiplied without any agreed method of control. This description of South African Upper Cretaceous ammonites is a good example of the new methods that have been applied during the past 25 years, involving accurate stratigraphical collecting and the use of single bed assemblages as a control to the species classification. It has been found repeatedly that the considerable morphological variation that has to be admitted to ammonite species, embraces many species and even genera of past ammonite systematists.

show that it is almost certainly the muscle that induces acetylcholine synthesis in the Schwann cell. The identity of the inducing factor(s) is, here, as elsewhere, unknown.

It is an exasperating fact that while the chemical mediators of induction in embryos remain unknown, most of the known and characterized growth factors discovered through assays *in vitro* have no well established role *in vivo*. The most recently discovered of these factors is a component of the brain and pituitary that causes proliferation of Schwann cells and astrocytes *in vitro*<sup>14</sup>. Brookes has now raised a monoclonal antibody against it, which will make it possible to purify and sequence it; and to discover what, if any, its function is *in vivo*. □

## Solar oscillations

from H.B. van der Raay

KNOWLEDGE of the Sun, our closest star, is based on observations of its surface properties. The temperature, magnetic field and constituents of the outer layers can be deduced by spectroscopy and, combining these data with estimates of size and mass, a model of the Sun's properties can be formulated. The model fits not only the observed surface properties but also predicts interior characteristics such as density and temperature. From these parameters and rates for the nuclear fusion reaction which converts hydrogen to helium and provides the energy output of the Sun the number of solar neutrinos associated with the nuclear burning may be readily found. An experimental verification of the standard solar model thus became possible. Unfortunately, as is well known, the experiment designed to detect these solar neutrinos failed to record the numbers predicted.

An alternative way to probe the solar interior is by the detection of solar oscillations in a manner analogous to terrestrial seismology. The pressure waves associated with the oscillations, especially if of long period, penetrate deeply into the

solar interior and convey information about the internal structure. Here again observations and predictions from the standard model appear contradictory. Does this imply that the theory is incorrect or is it the interpretation of the observations that is at fault?

Long period oscillations of the sun were discovered by Birmingham<sup>1</sup> and Crimean<sup>2</sup> groups, working independently, in 1976. Both groups measured the line of sight Doppler shifts of certain Fraunhofer absorption lines and, since observations were made on the integral solar disk, concluded that these observations corresponded to simple radial oscillations of the sun. The measured period of 160 minutes raised an immediate conflict with the standard solar model since if these were simple radial oscillations the longest period predictable was approximately 60 minutes. The Cambridge theorists<sup>3</sup>, however, pointed out that the observations could be interpreted in terms of more complex g mode oscillations.

Since these early observations, studies of line of sight velocities of the solar surface have continued. The Crimean group have found evidence that the 160 minute oscillation has persisted to the present day

with the same phase, although with a substantially decreased amplitude. This is confirmed by a group working at Stanford<sup>4</sup>. The Birmingham group have, however, failed to confirm this result and find many long period oscillations which vary in period, phase and amplitude from one day to the next<sup>5</sup>.

All these observations necessarily suffer from the fact that the sun is only visible for part of the day and, as a consequence, the data sets are modulated by a 24 hour period. Any periods found which are harmonics of a day thus need to be considered most critically. 160 minutes is exactly 1/9 of a day — could this oscillation appear simply as the result of the method of analysis? The Crimean and Stanford groups, aware of this possibility, point out that the period is now found to be 160.01 minutes.

At the other end of the time scale are the five minute oscillations first discovered by Leighton in 1960. A detailed study of this region over some three years by the Birmingham group<sup>6</sup>, showed that these five-minute ( $\sim 3$  mHz) oscillations had a well defined structure and consisted of  $>20$  well defined discrete frequencies with a mean spacing of alternate lines of 135.6  $\mu$ Hz. Interpreting these data in terms of the then current solar models Iben and Mahaffy<sup>7</sup> and Christensen-Dalsgaard *et al.*<sup>8</sup> suggested a heavy element abundance  $z \approx 0.004$  in contrast to the standard model value of  $z = 0.02$ .

The solution to the 24 hour modulation problem may be found in three ways: (a) by placing many observation stations around the globe, (b) by observing at one of the earth's poles, (c) by operating from a suitable space satellite. Each of these solutions have both advantages and disadvantages: (a) would require redundancy at any given longitude to overcome weather problems, (b) is subject to atmospheric effects as the sun is always close to the horizon, (c) includes all the technical problems associated with a space program. Also the costs involved increase rapidly as one proceeds from (a) to (c).

The polar solution has been taken by Grec *et al.* and is described in this issue of *Nature* (see p.541). The stresses of an austral summer were amply rewarded by the results of an excellent experiment which resulted in 120 hours of uninterrupted

observations. The preliminary analysis confirms the detailed structure and spacing found in the five-minute oscillation. However, those data relating to the longer periods do not show convincing evidence for the existence of a 160 minute oscillation. It is only when a superposed epoch analysis similar to that used by the Crimean and Stanford groups is used that the 160 minute period emerges. Admittedly the 24 hour modulation associated with daytime observation is no longer present in these data, but the earth does still rotate about its axis once every 24 hours, even at the pole. Hence any instrumental or atmospheric effects would have to be clearly eliminated.

Interpretation of the five-minute structure depends on the assignment of the modes observed. All the Doppler shift measurements are strongly biased to low order modes since the integral disk is observed. Hence it is customary to assume  $l_0, l_1 \dots$  modes, where  $l_0$  is the simple radial oscillation  $l_1$  alternate radial and axial expansions and contractions and higher  $l$  values correspond to more complex shape deformations. Once  $l$  has been assumed then for a given frequency  $\nu$ , the number of radial overtones,  $n$ , may be estimated and the results compared with theory.

In a revival of the standard solar model Christensen-Dalsgaard and Gough present a paper in the present issue of *Nature* (see p.544), in which the standard value for the

heavy element abundance is retained,  $z = 0.02$ , and the observational structure of the five-minute oscillations is fitted by taking into account the effect of the solar atmosphere. However it is clear from the models listed that these are very insensitive to the observed frequency separation. Indeed it appears that the only significant change in  $\Delta\nu$ , the frequency separation, occurs when low  $z$  values are considered. At the recent Eslab symposium<sup>9</sup> a mean spacing of  $135.2 \pm 0.2 \mu$ Hz was reported which would still appear to favour the  $z = 0.004$  value. A direct comparison of the predicted frequencies with the 25 which have now been measured to an accuracy of  $1:10^3$  may yield a more conclusive test as to which model to use.

All interpretation of the data depends critically on the correct identification of the mode concerned. This may be experimentally determined by considering two dimensional observations of the solar disk. Such work is at present in progress<sup>10</sup> and will hopefully resolve any mode identification problems. The experimental observations of independent groups have firmly established the discrete structure of the five-minute oscillations although the mode identification and reconciliation with theory is still unsatisfactory.

Clearly if we do not understand our own closest star, the implications on the whole field of cosmology are enormous, and continued efforts by both theorists and experimentalists are urgently required.

## Coronavirus come of age

from B.W.J. Mahy

ALMOST thirty years after the pioneering work of A.W. Gledhill and C.H. Andrewes at the Mill Hill laboratories established the essential features of murine hepatitis virus (MHV) infection (*Brit. J. exp. Pathol.* **32**, 559) the first international conference on the coronavirus group, of which MHV is the best studied member, has been held in Germany\*. The meeting consolidated much new and interesting data on a group of viruses responsible for a wide range of acute and chronic diseases. These presently include respiratory and enteric disease in humans, bronchitis in birds, transmissible gastroenteritis and encephalitis in pigs, diarrhoea in calves and dogs, peritonitis in cats, and both demyelinating encephalitis and hepatitis in rodents. A recent report of the isolation of coronaviruses from the brains of multiple sclerosis patients (Burks *et al.* *Science* **209**, 933; 1980) has intensified interest in the group.

During the first half of the meeting, on

structure and replication, it became clear that, in addition to the characteristic morphological features of the group, coronaviruses from whatever species are unified by the possession of a large infectious single-stranded genome of  $6$  to  $7 \times 10^6$  molecular weight. Both the mechanism of expression of this genome, and the protein products, have unique features. M.C. Lai (Los Angeles) for a murine coronavirus and S.I.T. Kennedy (La Jolla) working with avian infectious bronchitis, each presented evidence that the genome is positive-stranded, with a capped (m<sup>7</sup>G) 5'-terminus and a stretch of poly(A) at the 3'-terminus. In infected cells six virus-specific RNA species are consistently found, ranging in molecular weight from  $0.6 \times 10^6$  up to genome size. T<sub>1</sub> ribonuclease mapping studies (S.I.T. Kennedy and J.L. Leibowitz, La Jolla) show that these RNAs form a 'nested set', the sequence of each RNA being contained

B.W.J. Mahy is Huddersfield Lecturer in Special Pathology at the University of Cambridge.

\*An international symposium on the 'Biochemistry and Biology of Coronaviruses' sponsored by the Deutsche Forschungsgemeinschaft was held in the Institut für Virologie und Immunobiologie, University of Würzburg from October 15th to 18th, 1980.

within the sequences of all larger RNAs; the 3'-termini of all the RNAs are common, and they all extend inward from the 3' end of the genome. *In vitro* translation experiments by S. Siddell (Würzburg) and B. van der Zeijst (Utrecht) showed that each subgenomic RNA is a messenger species which specifies a single primary protein product translated from its unique 5'-terminal sequence. Nothing is known at present as to the mechanism by which these subgenomic RNAs are synthesised, although UV target size measurements suggest that each is independently initiated on a negative strand template, and not derived by processing from a larger species (van der Zeijst). A membrane-bound RNA-dependent RNA polymerase activity present in cells infected with a porcine coronavirus was described by D. Brian (Knoxville), but as yet no evidence as to the nature of replicative intermediate molecules has been obtained.

Of the three well-defined virion proteins, one is a 60K nucleocapsid protein phosphorylated by a virion-bound protein kinase, and the others are envelope glycoproteins. The largest (90K) forms the petal-like structures (peplomers) of the 'crown' (from which the group derives its names), and apparently has a conventional mode of synthesis similar to the glycoproteins of other enveloped viruses. The smaller glycoprotein (23K) is embedded in the envelope lipid bilayer, and is largely unaltered by treatment of the virus particle with bromelain, which removes the peplomers; this protein thus fulfils a similar role to that of the membrane protein of other enveloped viruses such as influenza. Glycosylation of this coronavirus membrane protein has unique features. R. Rott (Giessen) showed for a bovine coronavirus that the 23K protein contains no fucose or mannose. H. Niemann and H. Klenk (Giessen), P. Rottier (Utrecht) and K. Holmes (Bethesda) all reported that synthesis of the 23K glycoprotein is not inhibited by tunicamycin; this indicates that, in contrast to all other virus glycoproteins studied so far (including the 90K corona-virus protein) dolichol-linked N-acetylglucosamine plays no part in biosynthesis. L. Sturman (Albany) showed that in the presence of tunicamycin virus particles still matured, but were released from the cells as 'spikeless' virions lacking the 90K protein.

Comparisons between the genomic and subgenomic RNAs of coronaviruses differing in pathogenic potential or species of origin were reported by several workers. T<sub>1</sub> ribonuclease mapping studies by B. Lomniczi (Budapest) gave rise to at least 11 different genome RNA fingerprints within 13 isolates of avian coronavirus originally classified as infectious bronchitis by pathological criteria. However it is likely that this technique provides too fine an analysis of genome structure for useful strain comparisons. S. Weiss (Philadelphia) described the *in vitro*

## Molecular lines in the red

from a correspondent

THE FIRST OBSERVATIONS of molecular emission in the far infra-red (IR) from an interstellar cloud have been made by a team at the University of California (D.W. Watson, J.W.V. Storey, C.H. Townes, E.E. Haller and W.L. Hansen *Astrophys. J.* 239, L129; 1980). These observations were made from the NASA Kuiper Airborne Observatory in January 1980 at an altitude of 12.5 km, using a liquid helium-cooled Ge:Sb photodetector in a metal-mesh, scanning Fabry-Pérot interferometer. The two  $J = 21 \rightarrow 20$  and  $J = 22 \rightarrow 21$  rotational lines of CO were observed in emission at 124 and 119  $\mu\text{m}$  from the Kleinmann-Low region of the Orion molecular cloud. The CO molecule in interstellar clouds has previously been observed in the millimetre and submillimetre regions of the spectrum, where it has been shown to be one of the principal molecular species containing carbon in dense molecular clouds such as Orion. The significance of the new 124- and 119- $\mu\text{m}$  observations is that for these rotational transitions to be observable at all, the CO must be much

hotter (500–1,000K) than the temperature of the CO molecules observed in the microwave ( $\sim 100\text{K}$ ). These high temperatures indicate that the CO observed in the far IR is present in a post-shock gas, corroborating earlier evidence obtained from H<sub>2</sub> observations that a shock wave is propagating into the Orion cloud.

This observational technology opens up an entire new spectral range for observations of molecular species in the interstellar medium. Until now observations of interstellar clouds have been limited mainly to the microwave and radio regions at the long-wavelength end of the spectrum, and to the visible and near ultra-violet regions at the short end of the spectrum. The IR region of the spectrum is a rich arena for remote-sensing applications, but it has been essentially closed to interstellar observations by a combination of detector problems and atmospheric absorption. The development of far-IR techniques for observation of the interstellar medium increases the potential for new discoveries concerning the structure, dynamics, chemistry and evolution of interstellar clouds.  $\square$

synthesis of a representative DNA copy of the genome of MHV strain A59. Using this cDNA probe, she found considerable sequence homology with other murine coronaviruses and a low level of homology with 229E virus, a human coronavirus. Extension of such studies to the virus isolates from multiple sclerosis brain tissue, which were obtained by passage of the tissue in mice, should help to identify the origin of these agents.

The second half of the meeting was devoted to persistency and pathogenesis. Although little is known of the molecular mechanisms underlying organotropism and pathogenesis following coronavirus infection, some advances were reported. Coronavirus-induced disease is very dependent upon the age at infection, genetic background, and route of inoculation of the host. K. Pickel (Würzburg) showed that mice were fully susceptible to fatal JHM virus infection up to the age of 21 days, but thereafter became fully resistant. Resistance could be induced by transfer of immune spleen cells from adult mice to baby mice, or by priming of adult non-immune spleen cells in baby mice with UV-inactivated JHM virus, but not by non-immune spleen cells alone. R. Knobler (La Jolla) confirmed that fatal encephalomyelitis induced by JHM virus is an autosomal dominant trait; the ability of the virus to induce demyelinating lesions

depended upon the cell tropism of selected mutants to replicate in oligodendroglial cells. H. Wege (Würzburg) reported that injection of JHM *ts* mutants into preimmunised rats by the intracerebral route causes a high rate of subacute to chronic demyelinating disease with similarities to virus-induced demyelination in man. Rats survive normally after intraperitoneal injection of similar virus doses.

Several investigators have studied the mechanism of resistance at the cellular level. F. Bang (Baltimore), who had shown as early as 1960 that peritoneal macrophages taken from MHV resistant mice were also resistant to infection *in vitro*, now reported that macrophage resistance is also dependent upon associated lymphocyte action and may also involve interferon. Extension of these studies from macrophages to primary mouse hepatocyte monolayer cultures by H. Arnheiter (Zürich) confirmed that the hepatocytes were genetically resistant to virus infection as were the mice themselves. Although interferon treatment reduced virus titres in susceptible cell cultures, addition of anti-interferon antiserum did not augment the susceptibility of resistant hepatocyte cultures. Thus it can be concluded that such cells are intrinsically resistant to virus infection, though by what mechanism remains to be determined.

In contrast to other positive strand RNA viruses, the corona-viruses readily establish persistent infections in the host. For example, chronic hepatitis or chronic demyelination of the central nervous system occur with certain virus-host combinations. Not surprisingly, persistent infections are relatively easy to establish in cell culture *in vitro*, and such model systems have some unusual features. K. Holmes (Bethesda), N. Hirano (Morioka) and S. Stohman (Los Angeles) each reported that in cloned cell cultures persistently infected with MHV only 10–20 percent of the cells express coronavirus antigens detectable by immunofluorescence, but 100 percent are resistant to superinfection with homologous virus. G. Chaloner-Larsson (Ottawa) has obtained very similar results with a human

coronavirus (229E) persistent infection of L 132 cells. Further characterisation of such *in vitro* systems is sure to provide much-needed insight into the way these viruses establish such an intimate relationship with the host. Summing up the meeting, D. Tyrrell (Harrow) emphasised the very wide range of diseases now known to be caused by these viruses, and the value of their study as models of virus pathogenesis. As the meeting convener, V. ter Meulen (Würzburg) pointed out, virtually every laboratory currently working with coronaviruses was represented amongst the seventy participants, and the collective presentation of their data undoubtedly served to strengthen and unify their purpose in unraveling the molecular biology of this unique group of viruses.

transposition is reasonably low, it should be possible to build a *Drosophila* strain that lacks copia sequences. Young has made a start to this interesting, but very tedious experiment: at the time of the meeting a strain with only six copia sequences had been made and the flies were apparently no worse for their experience. Only time, and hard work, will tell whether or not copia sequences are necessary for some aspect of *Drosophila*'s existence.

The second genetic approach stems from the exciting discovery that at least one well known mutation (white-apricot) is associated with an insertion of copia into the white gene. B. Judd and P. Bingham (Research Triangle) have mapped this copia element within white to the same region as maps the *w<sup>ad</sup>* allele and W. Gehring's laboratory (Basel) has found that revertants of *w<sup>ad</sup>* may be accompanied by loss of the copia element from this site.

The role of the insertion of nomadic middle repeat sequences into genes as a cause of spontaneous mutation in *Drosophila* was also highlighted by the molecular study of the bithorax region. W. Bender (Caltech) has now cloned over 145 kilobase pairs of this region and has used these clones to analyse the nature of some of the many mutant bithorax genes. Two (*bxd<sup>1</sup>* and *bxd<sup>5</sup>*), both spontaneous in origin, result from large insertions (of about 10 kb) into the gene. Although the insertion sites are not identical they are reasonably close together and each insertion is a repetitive DNA sequence. A spontaneous reversion of *bxd* turns out to have lost most, though not all, of its insertion. It must be most gratifying to E. B. Lewis, who is responsible for the very detailed genetic analysis of this complex locus, to see how well the molecular analysis of these mutations is confirming the genetic data. For example, the dominant mutation *Chx* was recovered, after X-ray mutagenesis, together with a recessive *pbx* allele: Bender has now shown that *pbx* is a deletion and that the sequence removed from the *pbx* site has been inserted some kilobase pairs away in reverse orientation to give the *Chx* mutation. Reversion of *Chx* has been accompanied by an inversion broken within this inserted sequence.

It is to be hoped that the molecular analysis of long regions of the genome will throw some light on the old question of the relationship between genetic organisation and chromosome structure. P. Spierrer (Geneva) recounted his latest travels along the chromosome in the region of the genes coding for xanthine dehydrogenase (*rosy*) and acetyl cholinesterase. Over 300 kb of DNA (three 'Benders') have been covered and this spans eight polytene chromosome bands and as many characterised genes. As dramatically as any other this experiment demonstrates the variation in location of middle repeat DNA sequences. The DNA cloned for this walk came from two different 'wild type' stocks of *D.*

## Drosophila at Kolymbari

from M. Ashburner

FOR the second time the Greek Orthodox Academy at Kolymbari, on the northern shores of Crete, was host to a meeting of *Drosophila* biologists\*. Not surprisingly, the scientific sessions were dominated by discussions of the molecular structure of the *Drosophila* genome. Restriction maps and nucleotide sequences were so common that I am sure more than one participant considered that his colleagues, but naturally not himself, had fallen into the trap so carefully avoided by Dr Watson, of confusing hard work with hard thinking. Nevertheless some very interesting facts were brought to our attention: interesting if only for the reason that they were quite unexpected.

There can be little doubt that the major challenge to conventional genetic wisdom revealed by the molecular analysis of the genome of *Drosophila*, and other eukaryotes, has been the discovery of repeated DNA sequences of no fixed abode. The 'type' of these sequences, as far as *Drosophila* is concerned, is that dubbed 'copia', a sequence of some 5 kilobase pairs which is present, in the typical strain of *D. melanogaster*, roughly 30 times. Comparison of the chromosomal locations of this sequence in different strains of *D. melanogaster* has shown that these differ between, and even within, strains.

Studies on the sequence organisation of copia, and similar elements, by G. Rubin's laboratory (Harvard Medical School) have revealed striking similarities between copia, a dispersed middle repeat sequence of yeast known as Tyl, and integrated vertebrate retroviruses. Copia is flanked by

a direct terminal repeat of 276 base pairs and a comparison of the nucleotide sequence of sites into which copia has inserted reveal that insertion is accompanied by a direct duplication of five base pairs of the 'target' sequence. Other nomadic middle repeat sequences of *Drosophila* appear to have a similar overall organisation to copia but to generate duplications of the insertion site of different sizes (for example four or seven base pairs). The similarities between these elements and bacterial IS sequences are striking; whether these similarities reflect the mechanisms IS sequences and the nomadic eukaryotic elements use for transposition is not yet known.

Copia, and some other nomadic middle repeat sequences of *Drosophila*, were originally cloned by virtue of the fact that their RNA transcripts are particularly abundant, at least in tissue culture cells. Work in both M. Young's laboratory (Rockefeller University) and in Rubin's has now shown that several different transcripts complementary to copia can be found in cells: whether these can all come from any single copia sequence is not known. For many years the function of RNAs complementary to copia has been the subject of some considerable discussion. They are clearly not translated in proportion to their mass yet, as work by both Rubin and J. Lengyel (University of California, Los Angeles) has shown, these RNAs can be translated into polypeptides in a cell free system.

Two genetic approaches to understanding the function of these nomadic sequences were discussed at Kolymbari. Since different stocks of *D. melanogaster* differ in the location of their copia sequences, and since the frequency of copia

M. Ashburner is in the Department of Genetics, University of Cambridge.

*melanogaster*: Oregon-R and Canton-S. Overall seven different insertions of middle repeat DNA were found but none were in the same location in both stocks: indeed many were polymorphic within a stock. Yet for non-repetitive DNA these two stocks show only a fraction of a percent divergence in sequence.

A rather different type of transposable element in *Drosophila* was described by G. Ising (Lund). This element, called TE1, is huge, it carries at least two genes (white and roughest) normally adjacent in the X. It arose spontaneously some years ago as a transposition of  $w^a$  and  $rst^+$  from the X chromosome to chromosome two and, since then, has been merrily hopping around the genome with a frequency of about  $1:10^4$ . Ising has mapped over 150 different sites into which it has inserted, insertion often being accompanied by mutation of the 'target' gene. Just how TE1 moves, or how it can be lost altogether from the genome, is rather mysterious but there is hope that the cloning of one end of TE1 fortuitously inserted very near one of the heat shock genes (M. Goldberg, Basel) will help to solve this mystery.

As at Kolymbari two years ago the analysis of genes of known function, known at least in terms of their protein products, continues to give great pleasure to participants and onlookers alike. Those few genes in *Drosophila* whose activity is so dramatically induced by heat shock are by far the best known. Cloning has confirmed earlier genetic conclusions that those coding for the four small heat shock proteins are very closely linked. R. Morimoto (Harvard) described that their coding sequences are all contained within a 13 kb fragment. Detailed comparison of

the DNA sequences upstream of the 5' ends of these genes with those of genes coding for three other heat shock proteins is revealing homologies some 125 bases upstream from the 'TATA box' sequence.

The clones of the 'major' heat shock gene (Hsp70), a gene that is repeated at each of two different loci in *D. melanogaster*, are now beginning to be used for a number of quite different studies, for example of gene evolution (D. Ish-Horowicz, ICRF, London), nucleosome spacing (M. Noll, Basel) and chromatin organisation revealed in the pattern of sensitivity to nucleases (S. Elgin and C. Wu, Harvard). Yet early hopes that a comparison of the sequences adjacent to different Hsp70 copies would quickly reveal those sequences important for the control of transcription appear to have been too optimistic, since variant Hsp70 genes have been isolated that can be shown to be functional, yet lack a characteristic class of sequences normally found 5' to the coding region (M. E. Mirault, Geneva). On the other hand the conference heard from J. Liss (Cornell) that the insertion of a small (406 base pair) sequence, which includes the first 63 base pairs of the translated Hsp70 gene and material 5' to it, into a particular repetitive DNA sequence found adjacent to some Hsp70 genes results in the induction, by heat shock, of transcription of the middle repeat sequence.

Unfortunately, the function of the heat shock proteins remains unknown. Their importance for the cell in the recovery of normal protein synthesis after the heat shock was shown by S. Lindquist (Chicago). The incorporation of certain amino acid analogues into the heat shock

proteins apparently blocks their post-transcriptional processing and normal accumulation in the nucleus; it also blocks the recovery of normal protein synthesis after the heat shock. Lindquist suggests that normally these proteins may be nucleic acid binding proteins. Recently, rather similar responses to environmental shock have been found in organisms as different as yeast and man. A. Tissières (Geneva) discussed evidence from fingerprints of 'heat shock' proteins from different animals that indicates that at least Hsp70 may be conserved.

Progress is also slow in discovering the mechanisms of induction of heat shock protein synthesis. T. Kornberg (University of California, San Francisco) has characterised an *in vitro* system using isolated *Drosophila* tissue culture cell nuclei in which the *E. coli* RNA polymerase directed transcription of the heat shock genes is responsive to the addition of factors from heat shocked, but not control, cells. The nature of these factors (or factor) is yet to be elucidated.

Other genes that attracted attention at Kolymbari were those coding for the salivary gland 'glue' proteins and the proteins of the egg shell of *Drosophila*. Each had their surprises. A component of the salivary gland glue, known as SGS-4, is coded for by a gene on the X chromosome and is of interest for several reasons. G. Korge (Munich) has characterised mutations that normally fail to express this gene yet will do so when the mutant gene is made heterozygous with a wild type allele, at least under certain conditions. This is rather similar to the transvection affect described for the bithorax locus by E. B. Lewis 25 years ago. The coding region for SGS-4 has

## 100 years ago

Fanduri — a Dorey papuan

Epa — a Village of the Mahori papuans.

Pictures from "New Guinea: What I did and what I saw" by L. M. D'Alberty reported in *Nature* 23, 16 December, 153, 1880.

been cloned in Stanford and is being used for the analysis of this entire region of the genome by S. Beckendorf (University of California, Berkeley) and for detailed studies of the gene itself by M. Muskavitch (Stanford). A surprising result is that the transcript of SGS-4 differs in size in different strains of *Drosophila*. This results, it would appear, from the fact that within the coding sequence there is a 21 base pair sequence whose repetition frequency can vary between different SGS-4 alleles. Although nothing is known of the chemistry of the protein this must reflect a sequence of seven amino acids repeated a varying number of times.

The mutation characterised by Korge, that fails to make SGS-4 protein when homozygous turns out to be a small deletion, but of a sequence over 200 base pairs away from the 5' end of the messenger RNA. The importance of this region is indicated by the fact that two different expressed alleles of SGS-4 differ by a single

base pair substitution in this region and by a factor of two in the abundance of their mRNAs.

The egg shell protein genes, under study by A. Spradling (Carnegie Institution, Washington) and in F. C. Kafatos' laboratory (Harvard) also surprised us for they are amplified in the tissue in which they are expressed. Spradling has found that the amount of DNA amplified extends at least 30 kb on each side of the genes themselves, but the degree of amplification falls off, from a peak of some 60 fold, in both directions away from the coding sequences. This, and the fact that the amplified DNA has an identical restriction pattern to non-amplified DNA, may indicate that the process is chromosomal, rather than extra-chromosomal as in oocyte ribosomal genes in many organisms. Yet the Harvard laboratory (G. Thiroes and R. Griffin-Shea) have found that amplification of another pair of egg shell protein genes is accompanied by their

premature transcription; but that these early transcripts are not translated and, indeed, decay as development gets under way. Only at the appropriate developmental stage several hours later does transcription resume to produce mRNAs that are subsequently translated.

What is the meaning of this? It implies some relationship between amplification and early transcription and also indicates the existence of a translational control at the early developmental stage.

Like all good meetings, at the end there were far more questions than answers. As is right and proper we were treated to many very preliminary data whose place in the jigsaw puzzle is yet undiscovered. The great success of the Kolymbari meeting was in bringing together molecular and classical *Drosophila* biologists to discuss their data from their different perspectives and we can only hope that some of today's mysteries will be clearer to us when we next meet.

## Comets and the origin of life

from N.J. McNaughton and C.T. Pillinger

COMETS are the most spectacular bodies in our solar system and the anticipated return of Halley's Comet in 1985-6 has already proved a catalyst for increased cometary research. As the comet nucleus contains, perhaps with the exception of phosphorus, the necessary ingredients for life on this planet, the pundits of earthbound chemical evolution and cometary science found common ground at a recent colloquium\* entitled 'Comets and the origin of life'.

Although almost all of our observations of comets have been obtained from or near the Earth, the accumulated data yields a basic understanding of the structure, chemistry and physics of the comet nucleus and tails. Perhaps the most significant point to emerge from new observations is the apparent constancy of comet's chemical composition.

A'Hearn (University of Maryland) observed that the rate of production of certain chemical species, particularly CN, C<sub>2</sub>, C<sub>3</sub> and OH, from the comet nucleus near the sun is uniform irrespective of the type of comet and its gas to dust ratio. The spectroscopic continuums of comets of different ages are also strikingly similar (Donn, NASA-Goddard). It is not yet clear whether this uniformity is due to the nature of the chemical reactions in the coma or if it implies that comets are derived from a constant composition reservoir. How the latter interpretation fits with a recently announced theory for the origin of comets (Biermann *Royal Society Meeting on Planetary Exploration*, Munich, Nov. 4-5, 1980) is not clear. Biermann's new hypothesis predicts cometisimals as the

possible end product of a fragment of protosolar nebula collapsing in a relatively low magnetic flux. According to the same theory, planetary systems would be produced in a large magnetic flux and there seems to be no way for both planets and comets to be produced together.

The current interest in comets has promoted a shift in emphasis among the prebiotic synthesis investigators — low temperatures and photon or proton irradiation appear to be the order of the day. Reproducing cometary compositions and environments in the laboratory, the Maryland group and Greenberg (Leiden University, Netherlands) have synthesised 'life-like' organic molecules. Long chain hydrocarbons, nitrogenous compounds and carboxylic acids have been identified spectroscopically among the products of reactions carried out at temperatures as low as 15°K. Given that similar molecules could only be produced on the Earth under a strongly reducing protoatmosphere (which the Levine group from Virginia calculate would be short-lived due to the high reactivity and abundance of OH), the introduction of such molecules via comets into a less drastic protoatmosphere offers a real, and in some cases preferred, mechanism for the beginning of life on Earth. Speculations on this theme range from the controversial — Wickramasinghe (University of Cardiff) envisaging comets as the carriers of already living organisms — to efforts to calculate possible mass inputs (Lizcano-Aranjo, Houston).

Definitive evidence on the relationship between comets and the origin of life must

await the eventual laboratory analysis of cometary material. The identification of microscopic stratospheric and deep-sea particles of extraterrestrial origin by Brownlee (University of Washington) offers, however, the first real samples of probable cometary debris. The minute size and rarity of unaltered Brownlee particles preclude the use of most conventional analytical procedures, and substantial refinements to existing or even new techniques (such as the CD<sub>4</sub> carbon isotopic method pioneered at the University of Cambridge), are required before even the Brownlee particles can be fully exploited.

The alternative to analysing cometary material found in the terrestrial environment is *in situ* measurements from spacecraft. The planned NASA/ESA international mission to rendezvous with Halley's Comet which would have allowed analyses as sophisticated as those needed for origin of life studies will now not take place. ESA's fast flyby of Halley (the Giotto mission) will undoubtedly produce information on the composition of the gas and solid phases to fuel further laboratory based studies but is unlikely to provide definite answers to the question of whether comets were involved in the origin of life on Earth.

### CORRIGENDUM

Edward Herbert would like to point out that he was not the sole author of *Biosynthesis and processing of cellular and viral polypeptides* (News and Views, 13 November, 288, 115, 1980) and would like to acknowledge the co-authorship of Gunther Kreil (Salzburg) and the help of Carolyn Carter and Eckard Wimmer (Stoneybrook, New York).

N.J. McNaughton and C.T. Pillinger are in the Department of Earth Sciences, University of Cambridge.

# Solar oscillations: full disk observations from the geographic South Pole

Gérard Grec\*, Eric Fossat† & Martin Pomerantz‡

*Observing conditions at the geographic South Pole enable modes of global solar oscillations and theoretical models of the internal solar structure to be identified.*

THERE are only two methods available for probing the interior of the Sun to test the theoretical models of the internal solar structure. Such calculations have been based on externally observable parameters ( $M_{\odot}$ ,  $L_{\odot}$ ,  $R_{\odot}$ ,  $t_{\odot}$ ) plus some speculations regarding the relative abundances of certain elements, such as metals and helium<sup>1</sup>.

The first technique requires the exceedingly difficult measurement of neutrinos emanating from thermonuclear reactions in the solar core. After much effort, Davis<sup>2</sup> established an upper limit of the solar neutrino flux ( $1.75 \pm 0.4$  SNU) that is somewhat below original expectations. These neutrinos convey information only about the central region of the Sun, where the time scale of temporal variations is enormous ( $\sim 3 \times 10^7$  yr).

The second approach attempts to detect and identify normal modes of global solar oscillations arising from internal processes. These pulsations characterize phenomena in the layers in which dynamical processes can cause effects that produce visible manifestations on the solar surface<sup>3</sup>.

Efforts to detect global solar oscillations through observation of luminosity variations<sup>4-7</sup> were unsuccessful because the amplitudes are far smaller than the transparency fluctuations of the Earth's atmosphere.

Another technique utilizes continuous determinations of the apparent solar diameter<sup>8-12</sup>. These experiments have produced positive results which have been attributed to underestimates of the effects of atmospheric fluctuations<sup>13-16</sup>.

Finally, various Doppler shift measurements of large-scale velocity fields have been carried out either with spatial resolution or with integral light from the entire visible disk. These have usually involved continuous observations of various spectral lines by optical resonance techniques.

Fifteen years after the discovery of 5-min oscillations by Leighton<sup>17</sup> came the first incontrovertible observations of global solar pulsations by Deubner<sup>18</sup> who succeeded in resolving the diagnostic  $\kappa$ - $\omega$  diagram (or spatiotemporal power spectrum) into discrete lines. The periods were  $\sim 5$  min and the horizontal wavelengths typically  $1-3 \times 10^4$  km corresponding to spherical harmonics with high  $l$  values (typically a few hundred). These results subsequently proved that solar seismology is an exceedingly powerful diagnostic tool for investigating the solar interior<sup>19</sup>. The modes discovered by Deubner have provided information on layers located several thousand kilometres below the photosphere. The detection of lower-order modes is required for probing greater depths.

Thus, there is general agreement over the occurrence of solar pulsations with periods in the range of  $\sim 5$  min. In fact, a recent study has resolved some low-angular ( $l$ ), high-radial ( $n$ ) overtones into discrete lines of amplitudes  $0.1-0.3$  m s<sup>-1</sup> separated by an average uniform spacing of 67.8  $\mu$ Hz (ref. 20). However, for various reasons (including possible solar noise, interference

by the Earth's atmosphere and other local considerations and the severe problems in conducting these difficult observations at normal mid-latitude locations), the validity of reports of longer period global solar pulsations, especially one at 2 h 40 min (refs 21, 22), has not been universally accepted<sup>23-25</sup>.

## The polar solar observatory

The advantages of undertaking certain types of astronomical observations at the geographic South Pole became apparent<sup>26</sup> during a program of cosmic ray research in Antarctica<sup>27</sup>. More recently, we recognized that the South Pole enabled us to pursue the solar oscillation problem in conditions that cannot be duplicated anywhere else on Earth:

- (1) during the austral summer, the Sun remains essentially at a constant angular altitude, thereby eliminating the difficulties introduced by the day-night cycle;
- (2) uninterrupted data runs appreciably longer than those attainable elsewhere are feasible, thus significantly improving both the  $\omega$ -resolution and the potential for detecting long-period oscillations;
- (3) the Amundsen-Scott Station at the South Pole is, in fact, at an elevation corresponding to a pressure altitude of  $\sim 3,400$  m;
- (4) the atmosphere is colder than elsewhere, hence the precipitable water vapour content is exceedingly low, and the transparency is good, providing extended periods of coronal seeing;
- (5) the polar plateau constitutes an absolutely uniform terrain (a desert of snow) out to great distances in all directions;
- (6) the large trend due to the Earth's rotation, which can never be removed as perfectly as is required, is absent at the planet's rotational axis.

Consequently, an American-French programme was organized to conduct this experiment during the austral summer 1979-80. Only the main characteristics of the apparatus constructed for obtaining the required observations in the hostile polar environment ( $T \leq -30^\circ\text{C}$ ) will be summarized here.

A sodium optical resonance photoelectric spectrophotometer developed at Nice (France) for full disk measurements of the Doppler shifts in the 5,896-Na D1 line<sup>28</sup> was modified to operate in the rigorous conditions at the South Pole. A vertical telescope (8 cm,  $f/18$ ), specifically designed and constructed for this experiment at Bartol, provided two nonrotating solar images, one of which was focused on the guiding sensor array, the other on the spectrophotometer.

Extensive photography in H $\gamma$  during the preceding austral summer<sup>29</sup> revealed that the telescope completely satisfied the requirements for the present programme.

We attempted to create the best conditions possible by eliminating all potential man-made sources of spurious effects such as the local source of thermal turbulence arising from the

**Fig. 1** Power spectrum of the continuous 5-day full-disk Doppler shift measurements recorded at the South Pole from 31 December, 1979 to 5 January, 1980. The resolution of the power in the 3-mHz range into many discrete equidistant lines separated by  $68 \mu\text{Hz}$  indicates that global  $p$ -modes corresponding at least to  $l$  values of 0 and 1 are observed. Note that the small peaks around 2.4 mHz represent global oscillations with an amplitude  $<10 \text{ cm s}^{-1}$ , corresponding to motion of the solar radius  $<5 \text{ m}$ , or  $7 \times 10^{-6}$  arc s.

**Fig. 2** A superposed frequency analysis of the frequency range between 2.4 and 4.8 mHz reveals the average shape of spectral lines displayed in the power spectrum of Fig. 1. The horizontal axis indicates where the theory predicts the positions of  $l = 1, 2, 3$  and 4 modes if the one on the extreme right is assumed to be  $l = 0$ . The good agreement leaves no room for doubt. Note that the natural width of each separate mode indicates a  $Q$  value of the order of 600.

Amundsen-Scott station complex which would be seen at the same time every day, a site 8.1-km upwind from the base was selected. There, the well insulated  $3.5 \text{ m} \times 2.5 \text{ m}$  laboratory building mounted on a sled was installed in a deep trench. The wanigan was then enclosed by a plywood roof and vestibule walls fore and aft, and was buried in the snow. The telescope and instrument package were mounted on the surface 30 m away. A 300-m cable connected the observatory to the diesel-powered electrical generator positioned downwind with respect to the prevailing wind direction. The exhaust emerged practically at ambient temperature, and neither the generator nor the track vehicle utilized for transport produced any detectable atmospheric disturbance.

## Observations

Historical meteorological records and experience gained during 1978–79 made us hope for one 5-day period of uninterrupted optimal seeing during December–January. In fact, this did materialize, and the 5-day interval was extended to  $\sim 7$  days by remaining on the air during two brief cloudy periods, which did not interrupt the tracking. In addition, clean data (cloud free) were recorded during intervals of additional hours ranging from 5 to 10, yielding high-quality tape recordings covering more than 200 h.

## Data analysis and results

The definitive results of the analyses so far completed use part of the available data—basically the 5-day continuous run. The results mostly concern: (1) whether the widely discussed oscillation of period 160 min could be confirmed in the ideal conditions that prevail at South Pole; and (2) the investigation of the theoretically expected line spectrum of the 5-min oscillation.

Note that the noise level at all frequencies was significantly lower than has ever been attained previously, by about an order of magnitude.

## The 5-min range

Figure 1 shows the power spectrum of the 5-day data sample. It reveals that the power in the 3-mHz range is resolved into many equidistant peaks, separated by  $68.0 \mu\text{Hz}$ . This confirms the result published by Isaak's group<sup>20</sup>. This constant displacement of  $68 \mu\text{Hz}$  clearly indicates that modes of low degree with both odd and even values of  $l$  are observed, because the frequency separation between modes of high order with the same value of  $l$  is expected to be around  $130\text{--}145 \mu\text{Hz}$  (depending on the theoretical model)<sup>31</sup>.

Modes with values of  $l$  between 0 and 3 may possibly contribute substantially to the observed line spectrum. Each line

**Fig. 3** The low-frequency part of the power spectrum shown in Fig. 1. Its spiked structure is consistent with statistical departure around a broad, continuous spectrum. A spiked spectrum of oscillatory  $g$ -modes, a broad-band solar convective spectrum as well as a broad-band telluric spectrum could separately be responsible for this result.

would then contain contributions from modes with even  $l$  or odd  $l$  with almost coincident frequencies. The frequency separation between neighbouring modes with  $l = 0$  and  $l = 2$ , and with  $l = 1$  and  $l = 3$  is expected to be  $\sim 10 \mu\text{Hz}$  and  $16 \mu\text{Hz}$  respectively<sup>31</sup>. Indeed, many peaks in Fig. 1 seem to be split into two or more components. To verify the significance of this splitting, we have used the equidistance to obtain the average shape of odd and even peaks by a 'superposed frequency analysis' of the spectrum between 2.4 and 4.8  $\mu\text{Hz}$  for an interval equal to 136.0  $\mu\text{Hz}$ . Figure 2 shows the result of this analysis, and clearly indicates that all modes between  $l = 0$  and  $l = 3$  and possibly even  $l = 4$  contribute to the power spectrum. It is quite reassuring that the  $l = 3$  modes display a significantly lower amplitude due to the smearing effect of the full disk integration.

In addition to the identification of the spherical harmonics associated with the spectral peaks, another important result emerges from Fig. 2. The width of the four main peaks indicates a  $Q$  value of about 600, or a typical damping time of 2 days. Indeed, if shorter data samples, of, say, 12 h, are Fourier analysed, the energy present in a given spectral peak does not seem to be constant in time or regularly modulated as would be expected from overstable beating pulsations. Rather, an individual peak seems to be suddenly excited and then slowly damped over a 2-day interval, unless it is re-excited before this time. A more complete statistical analysis of this temporal behaviour, embracing the total amount of data, will be necessary, but it is already clear that these modes around the 5-min period have a damping time of about 2 days and are spasmodically excited.

### The intermediate frequency range

Figures 1 and 2 show the asymptotic behaviour of low degree global modes that must be predicted by solar models. Between 2.4 and 5 mHz the order  $n$  (the number of nodes along a solar radius in the vertical component of the displacement eigenfunction) must typically be between  $\sim 15$  and 35 for these peaks<sup>31</sup>. To be able to identify each peak with one given order would require the detection of  $p$  modes with longer periods, and if possible all modes until the fundamental, the period of which is expected to be of the order of 1 h. Figure 1 shows that peaks with approximately uniform separation can be followed, with the limit of noise, towards low frequencies below 1 mHz. The same type of superposed frequency analysis, described above, over the range 0.8–2.4 mHz, demonstrates that  $l = 0$ ,  $l = 1$  and  $l = 2$  normal modes may be present in this frequency interval, with a mean amplitude of less than  $3\text{--}5 \text{ cm s}^{-1}$ . Comparing this information with theoretical model predictions, one can be assured that, for example, the first peak which emerges significantly above the noise level near 2.23 mHz must be an

$l = 0\text{--}2$  pair with  $n = 15 \pm 1$ . To suppress the indicated uncertainty of the  $n$ -number definitely, the first four or five spherical harmonics must be identified, and this is more difficult because the asymptotic frequency equidistance prediction is no longer valid in the frequency range 0.3–0.8 mHz. We hope to be able to eliminate this ambiguity eventually by including the totality of recorded data.

### The long period range

For periods longer than 1 h, we obtain an increasing power spectrum with decreasing frequency. Figure 3 shows this long-period power spectrum, for periods between roughly 30 and 300 min. Its spiked structure is consistent with pure statistical fluctuations around a broad, continuous curve. Although it may contain some solar information from oscillatory gravity wave or broad-band convective spectrum, this result alone does not allow us to conclude that any spectral peak is characteristic of a long-period solar oscillation.

### The 160-min period
